**Pigmentary Degeneration of the Retina.**—Walter L. Pyle reports the case of a man fifty-four years old suffering from this affection, in whose history there were a number of interesting peculiarities. In an accurate and comprehensive family history extending back over a century, no record existed of any ocular trouble, with the exception of one case of retinal hemorrhage in a brother who was addicted to the abuse of alcohol. There had been no consanguinous marriages in the family. He was a healthy boy, but was troubled with night-blindness although his visual acuity was normal. Examination of the eyes showed characteristic signs of pigmentary degeneration of the retina. Except in the exact macular region, there were scattered over the whole fundus pigment-masses with interlacing processes resembling the Haversian canals of bone. The long-continued absorption of retinal pigment had rendered plainly visible the choroidal vessels, giving the familiar "wainscoted" effect. The retinal blood vessels had undergone hyaline thickening, reducing the size of the blood column, but apparently not interfering with the transparency. They were outlined with whitish streaks. The optic discs were dull, pale gray—waxy or parchment-like—in appearance, with but little blurring of their margins. Contiguous to the center of the posterior capsule of the lens there was a small opacity in each eye, but otherwise the media were clear. The fields of vision were reduced to within the 5° circle for white, and within the 3° circle for red, but the central acuity of corrected vision and color-perception remained remarkably acute. Response to the Abney pellet-test is prompt and accurate. There was very little nystagmus. The pupils reacted to light and accommodation. Despite this marked degree of retinitis pigmentosa and restricted union, the man was able to follow the calling of traveling salesman, covering the territory east of the Mississippi and making long journeys by day or night trains. Much of his ability to go about unassisted was due to a noteworthy compensatory development of the sense of touch and hearing, estimation of distance, sense of location, etc.

*The Lancet, August 1, 1903.*

**Fractured Clavicle with Ossific Union in Utero.**—E. Sydney Hawthorne reports a case of this kind coming under his observation on April 1 of the present year. The subject was a full-term child born after a normal labor. There was a small, hard, immovable, and painless tumor at the center of the right clavicle, which was not associated with crepitation or restriction of motion. The diagnosis was a fractured clavicle united by callus. Since that time the callus has been steadily absorbed until now the condition is that often found in green-stick fractures in the young. There was no history of injury to the mother during this pregnancy.

**Large Piece of Glass Embedded in the Orbit for Twenty Years Without Causing Symptoms; Removal.**—J. Hoggan Ewart reports this case, which came under his observation on July 4, 1903. The patient, who had a small sinus situated about 2 cm. above the inner canthus of the left eye, stated that twenty years ago a clock had fallen on her head, and the glass of the clock had broken and made a deep cut across and to the outer side of her left eye. The wound was sutured and gave no further trouble until three weeks before coming to him, at which time the skin broke and there was a slight watery discharge. A probe revealed the presence of a large piece of glass deeply embedded transversely above the eye. It was much cracked and its edges were quite sharp. On removal, it was found to measure 3 cm. in length, 1 cm. in breadth and 1.75 mm. in thickness.

**A Case of Recurrent Varioloid Rash Following Vaccination.**—R. W. C. Pierce reports an interesting and very puzzling case of eruption following vaccination. The subject was a boy of fifteen who was vaccinated on December 5, 1901, along with a large number of other boys in the same school. One other boy was vaccinated with lymph from the same tube, yet no other similar case developed. The vaccination was successful, and on returning home on December 16, he became ill with mumps. On December 24, or nineteen days after the vaccination, he had what was considered to be a typical attack of smallpox. He returned to school on February 22, 1902, quite well, but on March 4 again became ill, this time with what was diagnosed by four experienced physicians as varioloid because of the typical character and distribution of the lesions. By April 1 all of the pocks had "peeled" out, and he was discharged. As the boy had traveled about a good deal and several cases of smallpox of unknown origin had appeared in neighboring towns, the possibility of exposure to infection could not be completely excluded. On the other hand, against the theory of this being varioloid, were the facts that he had been ill two months before with what was taken to be smallpox, and had been successfully revaccinated three months previously. Apparently the two illnesses were identical. The case differed from the recorded ones of generalized vaccinia in that there was no recrudescence at or near the site of the original vesicles, and that the rash did not appear until nearly three weeks after vaccination. The behavior of the mother's vaccination points to an unusual family receptivity. The author suggests that the case may have an interesting bearing on the connection between variola and vaccinia.

*British Medical Journal, August 1, 1903.*

**A Very Simple Remedy for Tuberculosis.**—J. Dulbery writes that his attention was called, sime time ago, by an intelligent layman, to the use of raw carrots in the treatment of pulmonary tuberculosis. Though naturally skeptical, he consented to see some of the "cured" cases, with a view to publishing his conclusions for the benefit of the medical profession, and the impression he has derived so far is that the remedy is worth trying. It is his intention at a later stage to publish full particulars of the cases and the progress they have made. His reason for writing this preliminary note is to inquire whether any one has ever heard of this treatment, and to suggest that it be given a trial, considering that it is harmless.

**Swallowing a Pin Without Bad Results.**—M. Jenkins says that he was recently called to see a little girl who had swallowed a pin. On arrival he found a child two years old looking very blanched and excited, surrounded by a number of women, each one suggesting a different mode of treatment. On examining the child he could not find any place that caused her pain, but the mother was certain she had swallowed the pin, she having given it to her to play with a few minutes before, and the child having run to her partly choking. The mother was advised to give her a small quantity of very thick porridge at stated intervals, varying now and again with a little boiled rice, and to continue the same until further developments took place. The treatment was continued throughout the day, and the bowels acted late in the evening. They moved again the following day, at which time the pin, measuring an inch and a half in length, was passed without pain or discomfort.

*Münchener medicinische Wochenschrift, July 21, 1903.*

**A Case of General Infection with the Pneumobacillus.**—F. Jenssen reports a case of septicæmia, in which, during life, Friedlander's bacillus was cultivated from the blood. The case began as a multiple lobar pneumonia, but signs of general infection very soon appeared. At autopsy there was found a multiple pneumonia of both lower lobes with pleurisy; abscesses of the kidneys, liver, and spleen; and a diffuse purulent peritonitis due to rupture of the liver abscess. From all of these lesions the above-named bacillus was obtained and also from the fluid of the right shoulder-joint, from which it was cultivated in pure culture.

**A Case of General Infection with the Diphtheria Bacillus.**—Roosen-Runge's case was an empyema following a croupous pneumonia. The rib was resected, and from the pus pneumococci were cultivated in pure culture. For six days following, all went well, but there was then a sudden rise in temperature, followed by severe constitutional symptoms. At this time 20 c.c. of blood were taken from the median vein, and from it was cultivated a bacillus which was morphologically like the diphtheria bacillus and showed the same cultural and staining characteristics. Two days later a similar test gave the same result. Two days following, the patient died. At autopsy there was found an endocarditis, and in smears from the endocardium the above described bacillus was found to be abundantly present. Upon inoculation into guinea-pigs the bacillus was found to be non-pathogenic for these animals.

*Deutsche medicinische Wochenschrift, July 16, 1903.*

**Etiology and Therapy of Sclerosis of the Middle Ear.**—P. Stenger points out the important part which diseases of the nares and posterior nares (especially adenoids) play in the etiology of sclerosis of the middle ear. The early symptoms of such cases are often very obscure and slight, with the result that the process has been operative for a long time before the ear specialist is consulted. As is well known, treatment applied alone to the middle ear gives very unsatisfactory and uncertain results. It is of the utmost importance that, in conjunction with such treatment, attention should be directed to the nares and posterior nares, so that these cavities may be placed in the best possible condition. It is astonishing what results may be obtained from the latter measures alone. This is strongly exemplified in two cases of long standing, which are reported in detail.

*Berliner klinische Wochenschrift, July 20, 1903.*

**Biliary Colic without Gallstones.**—Hermann Krukenberg reports two cases of typical biliary colic which were operated upon, but in which no gallstones were found. In both the gall-bladder was exceptionally movable and might be designated as a "wandering" gall-bladder. It would seem certain that the attacks of colic were due to the great movability of this organ. In both cases the gall-bladder was made fast to the abdominal wall, and following the operation there were no further attacks.

**Pathogenesis of Pertussis.**—G. Arnheim has recently studied 150 cases and isolated therefrom a short influenza-like bacillus which refuses to grow upon the ordinary culture media, except in the presence of hæmoglobin. In the fatal cases the mucous membrane of the trachea and bronchi was in a state of advanced catarrhal inflammation. Recent investigations have shown that these mucous membranes are extremely rich in nervous elements, and it is probable that the violent attacks of coughing are produced through the irritation of these nerve elements by the toxins of the causative microorganisms—such irritation being conveyed to the coughing center in the floor of the fourth ventricle. Animal inoculations were carried on with cultures of the bacilli isolated, but these were without exception negative.

**Pseudotubercle Bacilli in a Case of Bronchiectasia.**—R. Milchner reports a case of bronchiectasia which was diagnosed as pulmonary tuberculosis, both upon the ground of the clinical symptoms and because of the presence in the sputum of morphological tubercle bacilli which retained the carbol-fuchsin stain after acid decolorization. Upon autopsy no gross or minute tuberculous lesions were found, and the correct diagnosis of the case was then first made. Sections of the involved lung tissue, which had been previously hardened in alcohol and formalin, were stained for tubercle bacilli, but none of these organisms were found. Fortunately some of the sputum of the patient had been preserved. Some of this was placed for a short time in alcohol and formalin, and

then stained for tubercle bacilli, the result being negative, although sputum from the same specimen which was not put in the alcohol and formalin showed apparently the presence of tubercle bacilli. Since genuine tubercle bacilli do not lose their staining properties when submitted to the action of alcohol and formalin, there can be no doubt but that the bacilli here present were pseudo-tubercle bacilli, and the fact is emphasized that submitting the specimen to the action of alcohol and formalin is a valuable method in the differentiation of pseudo from genuine tubercle bacilli.

*French and Italian Journals.*

**The Chemical Diagnosis of Hyperchlorhydria.**—Léon Meunier considers that the estimation of the total acidity and the hydrochloric acidity is not sufficient in deciding whether there is hyperchlorhydria of the gastric juice. The gastric juice, after Ewald's diet, is to be considered hyperchlorhydric only if with exaggerated or even normal chlorhydric acidity, it also contains in solution: (1) Sugar stuff reducing Fehling's solution, which, estimated in dextrose, will be less than 10 grams per 1,000 cubic centimeters, or better yet, (2) Soluble substances derived from starch, which, when transformed into dextrose, will yield an amount less than 20 grams per 1,000 cubic centimeters.—*La Presse Médicale*, July 22, 1903.

**Fermentation of the Fæces.**—A. Habel has found, from his investigations, that all functional or organic intestinal troubles result in fermentation, and holds that this fact may be of service in the diagnosis of dyspepsia from fermentation and (by a comparison of the degree of intensity of the process) in deciding the degree of functional change in the intestines. the differential diagnosis of organic and functional affections, and sometimes as an aid in determining whether certain pathological phenomena are due to intestinal or to other causes. The author disclaims the idea of being dogmatic, but merely suggests the utility of the measure, and says that he intends to carry on his researches upon the subject.—*La Presse Médicale*, July 18, 1903.

**Serous Cyst of the Appendix.**—R. Chevrier reports the case of a man who complained of attacks of pain in the right iliac fossa. These were not accompanied by a rise of temperature, nor did they interfere with the peristaltic movements of the intestines. The patient had only slight nausea. In fact, the only symptom of appendicitis was the localized pain. An operation was, however, decided on, and the appendix found to be free, somewhat longer than usual, and presenting in its central portion a swelling about the size of a walnut. On examination this was found to be a cystic cavity filled with serous fluid, not communicating with the appendix. The latter was not thickened, nor its tissues discolored. A microscopic examination was not made, as through some oversight the specimen was not preserved.—*La Revue Médicale du Canada*, July 8, 1903.

**Milk Diet and Ordinary Diet in Dyspeptics.**—M. G. Bardet concludes, from a detailed study of the subject, that hypersthenic dyspepsia is a purely functional affection, due to an excess of alimentation in persons incapable of transforming any more foodstuffs than their organisms absolutely need. It can be cured only by regulating the amount of food taken and by suppressing all irritating alimentation. No other medicines are needed than the earthy alkalies and sometimes anodynes. The majority of individuals are undoubtedly capable of absorbing three or four times the amount of nourishment which they really need; this proves that they have active livers, but a day will surely come, toward the fiftieth year of life, when they will pay by the wholesale for these daily excesses. Hypersthenia is a veritable boon in these cases, dyspepsia being a means of defence for the organism, if properly understood and treated—*Bulletin Général de Thérapeutique*, July 15, 1903.

**The Defensive Functions of the Greater Mesentery.**—Raffaele Pirone states that: (1) A spleen which has undergone necrosis from ligature in mass of the blood vessels becomes surrounded by the mesentery, which, because of the inflammatory process arising in it, rapidly forms connective tissue which does not merely encapsulate the spleen, but invades it. The endothelial cells of the membrane are transformed into macrophages which carry away the detritus of the gradually destroyed organ. Owing to this double plastic and phagocytic action, the mesentery ends by completely obliterating the spleen; behaving toward it as the vasal endothelium behaves in the organization of a thrombus. (2) Following the extirpation of the spleen, no histological changes are found in the mesentery indicating a vicarious lymphoid transformation of this organ. (3) The greater mesentery exhibits a vigilant protective action, which, under given circumstances, acquires the value of a true means of defence to the peritoneal cavity, and consequently to the whole organism.—*La Riforma Medica*, July 15, 1903.

**The Effects of Sea Air and Sea Bathing on the Phenomena of Nutrition.**—A. Robin and M. Binet conclude their study of the subject by a consideration of the indications and contraindications of this form of treatment. Sea baths have a stimulating effect on metabolism, and are therefore indicated when this effect is needed, but they are contraindicated in phthisis. They are indicated in rachitis, lymphatic troubles, scrofula, and tuberculosis of the bones and the ganglia, provided that organic destruction is not more active than processes of repair. They are indicated in anæmia and chlorosis when nutritive exchanges and oxidation are diminished, but contraindicated when these processes are over-active. Indicated in gout, especially if supplemented by suitable diet and hygiene; in chronic autointoxication of gastro-intestinal origin, in hyposthenic dyspepsia, in neurasthenia accompanied by phosphaturia, in the nervous conditions following fevers, and in certain cases of diabetes in which oxidation of the nitrogenous substances is diminished, and the relation of the total phosphoric acid to the total nitrogen tends to be raised.—*Archives Générales de Médecine*, July 21, 1903.

**Experimental Pathology of the Kidneys; Nephrectomy and Unilateral Ureterostenosis.**—Paolo Fiori has found that unilateral ureterostenosis provokes renal and general phenomena; the first are shown by oliguria, sometimes anuria albuminuria, hæmaturia, and a diminished elimination of urea and the salts of potash, and histologically by congestion, hemorrhages and degeneration of the epithelium; the second by emaciation. Disturbances of the urinary function are usually transitory, but may be prolonged or recur after a lapse of time. In ureterostenosis the general trophic changes are the chief characteristic; in nephrectomy the changes in the general condition are less marked. In both conditions other factors may concur to the alteration of the general condition; among others, functional insufficiency, and molecular lesions of the more highly differential cells. The remaining kidney may be the starting point of abnormal products from the elaboration or disintegration of cells. It is very possible that the protective internal secretions may become insufficient when we suppress or mutilate a kidney, and that while in nephrectomy compensation occurs fairly rapidly and is complete in ureterostenosis, the functions are neutralized by the greater amount of circulating poisons.—*Il Policlinico*, June, 1903.

---

**Phthisis in Laundresses.**—In the report of the Chief Inspector of Factories for Great Britain for 1902 the prevalence of phthisis among laundresses is touched upon. Among laundresses admitted into the Wandsworth and Clapham Infirmary during 1899 and 1900, phthisis cases formed 8.7 per cent. of the total admitted, while in the class of women other than laundresses the percentage was 5.3. In the Isleworth Infirmary during the same period the percentages were 10.9 and 4.5 respectively. Pulmonary phthisis is most marked in females from fifteen to twenty-five years of age.—*British Medical Journal*.

**Rare Ocular Manifestations of Venereal Disease.**—M. T. Yarr reports three unusual cases. Case 1 was that of a boy of eighteen years with a chancre of the eyelid. The inner third of the lower lid was irregularly eroded, and the whole depth of the lid was swollen and indurated. On eversion a pinkish-yellow, granular-looking, glazed ulcer with raised edges could be seen extending to the bottom of the fornix. There was practically no discharge, and the bulbar conjunctiva was unaffected. The condition was of four weeks' duration, and the diagnosis of chancre was confirmed by the appearance of the rash two weeks later. Recovery quickly ensued under the use of mercurial inunctions and boric-acid washes Case 2 was one of interstitial keratitis due to acquired syphilis. Infection had occurred five years previously. Case 3 was one of gonorrhœal iritis. Yarr says that while this condition may not be very rare, it is seldom made out. Gonorrhœal rheumatism supervened in this case and recovery of vision was not complete. The eventual local condition, as in two other similar cases seen by the author, was one of numerous thready synechiæ, grayish-green effused lymph, and a tendency to involve the pupillary edge of the iris chiefly, leaving the rest but slightly involved.—*Journal Royal Army Medical Corps.*

**Special Report to the Medical Record.**

(Continued from page 237.)

### SECTION OF TROPICAL MEDICINE.

*Wednesday, July 29—First Day.*

**President's Address.**—The President, G. H. F. NUTTALL, M.D., Ph.D., of Cambridge, remarked that there had been some doubt as to the continuance of a special section for tropical diseases, but that the British Medical Association could hardly call itself up to date without this section—recent work in tropical diseases was amongst the most important work ever done in medicine. The discoveries made with regard to malaria and yellow fever showed what lay in the power of this branch. New workers who want to make discoveries need but go to the Tropics. However, there were many diseases in temperate climates which, studied here with every convenience, would greatly help the elucidation of other similar diseases in the Tropics the investigation of which must necessarily be carried out under great difficulties. Last year, while studying a common horse-fly, *Stomoxys calcitrans*, the speaker had discovered a filaria in the head of this fly, a filaria not unlike *F. Bancrofti*, the life history of which had been so admirably worked out by Manson. The filaria found in *Stomoxys* had been described several years ago, but looking for its intermediate host he was able to find it in cattle. He was studying *Stomoxys* because it had been accused of transmitting the trypanosome of so-called surra in the Philippine Islands. All experiments made with this fly and with nagana infected animals at Cambridge proved negative, but he mentioned the finding of the filaria in *Stomoxys* to show how tropical diseases may be elucidated by the investigations of other similar diseases quite common in Europe.

**Disposal of Excreta in the Tropics.**—Prof. W. Y. SIMPSON, M.D., F.R.C.P., of London, opened the discussion on this subject. In England, he said, disposal of sewage was a term generally employed to represent its treatment for purification. It was at this stage that most of the difficulties connected with sewage disposal had arisen in this country, for as a rule those connected with collection and removal had been more or less satisfactorily overcome. In the Tropics it was different, and the term had a wider meaning and included collection, removal, and purification. It was obvious that there was little use of elaborate systems of purification in the last stage if the excreta were not properly dealt with or disposed of in the first two stages, and as a consequence a large quantity was allowed to remain and pollute the soil in close proximity to the dwellings. Indeed, the first two stages were, by far, the most important in the Tropics.

The Chinese, especially of Southern China, were probably the most careful of all nations in the collection, removal and disposal of excreta, while they were perhaps the most careless in the removal and disposal of garbage and waste water. The solicitude displayed in the collection, removal, and disposal of the excreta was not, however, based on any health consideration, but because among a people representing an ancient civilization agricultural skill and knowledge had been brought to a high degree of development. The value of the excreta as manure was to such an extent appreciated that the passer by was deemed to confer a favor by urinating in the receptacle provided near the shop or dwelling for that purpose. To own a public latrine in China was almost as lucrative a business as to own a pawnshop. Nothing under such a régime was wasted. In the villages the latrines were openings immediately over large cemented cesspools, the contents of which, to all appearances underwent certain bacterial changes similar to those in the recently introduced septic tank in England, for when emptied and discharged on the adjacent fields or into boats there was no deposit, but the whole seemed to be in a liquid state. The boats conveyed the sewage to the farmers, who stored it in similar cesspits and applied it to the land. It was seldom that fresh excreta were used.

For villages in the Tropics the Chinese method of dealing with the excreta seemed by far the most practicable and the most healthy so long as the cesspools and the latrines over them were well raised above the ground and protected against flood water and rain water.

It was the collection and removal of excreta which were so manifestly defective in the Tropics. As practical sanitarians, it was necessary to grasp the fact that it was not always necessary to introduce new methods or even European methods, on the contrary excellent results were often obtained by the old method or some modification of it, so long as the hygienic principles of the west were followed. There was nothing to be gained by inveighing against manual methods when the character and habits of the population allowed of no others.

As regarded removal of excreta, it might be broadly stated that no town of over 10,000 or 15,000 inhabitants could deal satisfactorily with the removal of its excreta other than by a system of pipes. This need not involve an elaborate system of sewerage. The system which seemed most suitable for a small town with a mixed population was a pail system, with numerous small depots dotted at convenient distances over different parts of the town, where the excreta and slops from the houses in the vicinity could be emptied and immediately conveyed by pipes to the outfall, where the product was to be treated.

Each district depot might be considered to be a large watercloset which, instead of serving one house, served a group of houses in the neighborhood. Belonging to the local authority and under its exclusive control, they could be fitted with flushing or disinfecting arrangements. These depots would allow of the removal of excreta being effected expeditiously without carts and with a small staff.

In Calcutta, in the European quarter, there was a depot in every compound by which the sewage of the house could be removed by gravitation to the outfall—as to the final disposal or treatment of excreta in the Tropics the only practical method was application to the land, unless it was a town situated on the sea and the currents were such as to carry the excreta away to sea. The application to land appealed to an agricultural people. The only question that might arise was whether the excreta should be applied direct to the land at once or undergo some form of preparation—although in favor of preparation according to the Chinese method, or the septic-tank system by which the putrefactive organisms get full play and destroy disease germs, yet Dr. Simpson was inclined to think that the application of fresh excreta to land could be carried out under favorable circumstances in the Tropics without the slightest danger of spreading disease, provided certain precautions were taken.

As to the preparation of the sewage before it was applied to the land, probably the system most suited to the Tropics was the septic-tank, in that the excreta were protected from flies. After a fairly prolonged exposure in the septic-tanks the excreta could be applied with advantage to the land direct in the dry season.

Dr. ANDREW DUNCAN continued the discussion by the reading of a paper in which he advocated either the system proposed by Prof. Vivian Poore or incineration

**Influence of the Septic Tank on Pathogenic Bacteria.**—Dr. LEONARD ROGERS, captain in the India Medical Service, followed with a paper on this subject. In India at the present time the septic-tank process was beginning to be introduced in various places. Captain Rogers, at the request of the Government of Bengal, had carried out some bacteriological investigations to try and ascertain the effect of the process on pathogenic bacteria. He found that the septic-tank process was inimical to most

of the pathogenic organisms tested for; that is to say, the typhoid bacillus, comma bacillus of cholera, staphylococcus, streptococcus, Micrococcus melitensi, Shiga bacillus of dysentery, and plague bacillus, but not to the anthrax bacillus, doubtless owing to the resistance of the spores. On the other hand even small quantities of the effluent from the tanks showed both the Bacillus enteritidis sporogenes and streptococci, so that it could not be considered as by any means free from pathogenic bacilli, and even after such treatment it would not be safe to discharge it in any place within draining distance of water which might possibly be used for drinking purposes.

Dr. H. Marcus Fernando of Colombo spoke of difficulties with regard to the disposal of excreta in Ceylon on account of the heavy rainfall. In many places the natives would not eat vegetables grown on sewage farms.

Dr. W. B. Clarke of Barbados described the cesspits of Barbados and asked whether sunlight might not have some beneficial action on sewage.

Fleet-Surgeon P. W. Bassett-Smith, R. N., drew attention to the widespread diffusion of the ova of intestinal parasites by means of sewage applied to land.

Sir Patrick Manson supplied details concerning the commerce of fecal matter and urine in China.

Dr. F. M. Sandwith of Cairo said that though he had tried to get the authorities in Egypt to introduce a water-drainage system and still thought it the best system of removal for towns, he felt bound to say that he had never seen any cases of epidemic disease which could be traced directly to good or bad cesspools. It ought to be understood definitely that all stools derived from patients suffering from typhoid fever, cholera, dysentery, ankylostomiasis, and perhaps plague, should be thoroughly disinfected before being thrown into the cesspool.

Dr. L. W. Sambon of London said the pail and cesspool system was a very old institution in Italy. Indeed it could be traced to the Ancient Romans. It was still very prevalent throughout the Peninsula. The sewage from the cesspits was finally applied to the land as manure. The speaker strongly condemned the application of sewage, and more especially of fresh excreta, to rapidly growing vegetables that were eaten raw, such as salads and radishes—repeated washing did not render such vegetables sterile and they might be a fruitful cause of disease dissemination. He mentioned an epidemic of typhoid fever in Naples which was traced to the consumption of salads manured with the contents of a cesspool in which typhoid stools had been emptied.

Dr. C. Christy drew attention to the importance of preventing the access of flies to cesspools.

Mr. J. Cantlie, F.R.C.S., of London, said that throwing sewage into the sea was by no means wasting it as some thought, and he mentioned the record takings of fish at Yarmouth which followed the throwing into the sea of 30,000 condemned carcasses of sheep from New Zealand.

Dr. G. H. F. Nuttall of Cambridge endorsed Dr. Sambon's caution that vegetables to be eaten raw should not be treated with human excreta. He mentioned the observations made during the Spanish-American War with regard to the connection between flies and typhoid fever.

Professor Simpson concluded by stating that the favoring of cesspools in large places always entailed badly kept ones amongst the poorer people. He thought that care should be taken with regard to the application of sewage to particular plants, the case of the epidemic mentioned by Dr. Sambon was very interesting, but he thought that under proper supervision there could be no danger.

**Sprue, Primary and Secondary, with Special Reference to the Blood Changes Found.**—Fleet-Surgeon P. W. Bassett-Smith, R. N., read a paper on this subject, reporting a number of illustrative cases. Sprue, he said, was a form of disease which one would expect to find frequently in the Navy, so large a fleet being now maintained on the China seas, taking up one of the most prolific endemic areas. Curiously enough, however, few cases appeared in the returns. The American surgeons, from a great experience of the disease in the Philippines, were of the opinion that it was not properly a specific disease, but only a condition produced after attacks of dysentery, probably caused by certain definite forms of bacilli belonging to the colon group which they were able to isolate from the stools. The speaker believed that sprue was a chronic inflammatory condition (causing cirrhotic changes in the mucous membranes) of bacterial origin; giving rise to a diminished supply of those nitrogenous products which were required in the formation of the red cells. He said he wished particularly to draw attention to the characters of the anæmia which this disease produced, and to point out that if recovery were to take place, it must be by raising the oxygenizing agents, viz., the red cells in the blood, to their normal level. The blood in sprue resembled that of pernicious anæmia, except that the hæmoglobin value of the cells was also reduced and megaloblasts were not present.

In the treatment of the disease, the speaker employed a milk diet, followed by clear soups, egg flips, and raw meat juice, according to the condition of stools. Medicinally he had given salol, Dover's powder, arsenic, iron, and oxgall; also stimulating expectorants were given for relief of the cough.

Sir Patrick Manson said he wished that cases of sprue were better studied, even in this country where, in people returning from the tropics, the disease lasted long enough for investigation. As to treatment, there was no one particular line to be followed as a routine. Milk diet did well in many cases. He had seen excellent results from mixed diet and likewise excellent results from a pure meat diet or from a pure fruit diet. He now placed the patient on milk diet; if this failed it was substituted by a diet of meat juice; if this also failed, a mixed diet was tried or a fruit diet. The result of fruit diet was admirably illustrated by a case he recently had at the London School of Tropical Medicine. The patient was over fifty years of age, at which time of life the prognosis in cases of sprue is always exceedingly grave. The patient was first treated with little benefit by milk diet and other special diets, finally strawberries began to come in and the patient was put on a diet of this fruit at a considerable expense. The stools at once improved and the patient was soon restored to health. This was not the only case in which recovery followed the use of strawberries. This speaker looked upon this as a decided advance in the treatment of sprue; another advance was the hypodermic use of arsenic and iron.

Mr. James Cantlie advocated the meat treatment and suggested that the acrid oils used for cooking in China might have something to do with the disease.

Dr. K. Goodboy stated that he had been making a bacteriological study of sprue cases, but that, so far, his observations were contradictory. He thought the treatment of the mouth lesions was very important.

Dr. L. W. Sambon wondered how any one could doubt the specific nature of sprue. The disease had well marked specific symptoms, ran a peculiar course, showed typical anatomical lesions, and had a definite geographical distribution. Perhaps the most important indication of its specific nature was the fact that the disease might manifest itself several months after the endemic area had been left, but only in those who had dwelt within this endemic area, and it never followed dysentery or other intestinal disorders in people from other tropical colonies where dysentery was common, but sprue unknown. Another important fact was the almost entire absence of the disease in the Navy, notwithstanding the large fleet maintained in the China seas.

Dr. C. Christy of Liverpool then read a short paper on "Entrance of the Malaria Spore within the Red Cells."

SECTION OF MEDICINE.

*Wednesday, July 29—First Day.*

**The Medical Treatment of Inflammations in the Cæcal Region.**—Dr. PAUL CHAPMAN of Hereford opened the discussion on this subject. The question of need for operation in appendicitis and the responsibility of the physician in attempting to decide were first alluded to If a characteristic history of previous attacks were obtained and a tumor were distinctly palpable then an operation was indicated, but the frequency of recovery without operation was emphasized. In those cases in which there was considerable dulness and obvious inflammation in the cæcal region the treatment should be more often expectant than it was prone to be at the present time. The old plan of giving saline aperients,with rest, and suitable diet was, if possible, to be tried in the first instance.

Dr. H.W. KING of Chester also thought that in many cases of inflammation in the cæcal region the patients would make a more satisfactory recovery without operation. Sedatives with the limitation of food in the presence of vomiting and other urgent symptoms, were in his opinion the chief indications in the first instance. In subacute cases he would give an aperient at once, but in acute cases he could give none. He had found the exhibition of belladonna with an aperient of very great value.

Dr. T. D. SAVILL of London divided the treatment of appendicitis into preventive, remedial. and surgical. A principal part of the preventive treatment of appendicitis was the treatment of chronic catarrhal colitis. This was chiefly by irrigation, particularly with a weak solution of chinosol or silver nitrate. As regards appendicitis, if the patient's pulse were under 100 or the temperature not raised he would temporize in operation. Opium he considered should not be given for as long as possible; it masked symptoms. He urged also that operation should not be delayed too long. He preferred to have a surgeon brought into contact with the case as soon as possible.

Dr. W. COLLIER of Oxford had hoped to hear more said regarding inflammation in the cæcal region other than appendicitis. He referred to a paper by Mr. A. W. Mayo Robson in which it was maintained that an operation should be performed as soon as a diagnosis of appendicitis had been made. But he had seen, in general practice, many slight and speedily recovering cases. The quality of surgical aid available was an important factor. In cases of mild appendicitis with a well-formed tumor in the right iliac region recovery had frequently occurred in the past. Now the tendency was to provide against risks to the practitioner's reputation by leaving the case to the surgeon. The disadvantages of operation were alluded to, such as hernia and pain in the cicatrix.

Dr. STRATON of Salisbury believed that many of the cases of appendicitis recovering were cases of colitis, the appendix undergoing enlargement as the tonsil did in response to microorganismal influence. Whenever suppuration had occurred, however, operation was indicated.

Professor SAUNDBY of Birmingham referred to a paper read by the late Mr. Lawson Tait, who held that it was reprehensible for a physician to have a case of serious appendicitis without having surgical opinion on the case, and described a consecutive series of thirteen hospital cases of appendicitis which recovered without operation. If there were any reason to think that pus were present operation should be done. If the attendant were in doubt, a leucocyte count should be made, and if there were an excess of leucocytes with continued pyrexia, operation might be done. Permission should not be given to the patient to resume ordinary life so long as a lump could be found in the right iliac region. Such cases should certainly be operated on, in view of the risk of an indolent abscess undergoing rupture and setting up fatal septic peritonitis. When a relapse had occurred operation was indicated.

Dr. W. J. TYSON of Folkestone thought this subject was essentially a combined question of medicine and surgery. At present the cases were too apt to become purely surgical. Many patients in whom relapses had occurred, twice at any rate, got well. From the beginning and in the early stages the case was medical. Careful attention to diet and relief of constipation meant a diminution of serious cases. In doubtful cases a consultation was particularly required. In the future the origin of the disease should be more carefully considered with a view to prevention.

Dr. MICHAEL FOSTER of London alluded to thc preliminary catarrh of the colon, which was apt to become mucous and even membranous colitis. Of thirty cases of membranous colitis under his observation, in four appendicitis developed; in one of these the appendix was removed, in another an abscess burst by the bowel, in a third case the appendix was removed, and in the fourth it was not. In two of the cases at least the colitis was not affected. In the treatment of the colitis overdieting should be avoided, but a full plain diet was indicated.

Dr. MAC PHEDRAN of Toronto thought the medical treatment was rest, physical and physiological, within some cases leeching over the cæcal region. The important aid in diagnosis in doubtful cases of suppuration which was furnished by a leucocyte count was emphasized. Operation he considered should be performed within the first few days, or if not then not until much later when adhesions had formed. It was not always in the latter case necessary to remove the abscess, merely draining the abscess was sufficient.

Dr. O'DELL of Torquay maintained that the physician and surgeon should share responsibility in the management of appendicitis cases. The dictum of Sir Frederick Treves that an operation should be done after the occurrence of a second attack was a sound one.

**A Sphygmocardiograph.**—Dr. PAUL CHAPMAN of Hereford then gave a demonstration of an instrument for obtaining simultaneous heart and pulse tracings, and an easy method of obtaining a tracing from the end of the index-finger.

**Treatment of Paralysis of the Upper Extremities by Cross Union of the Nerve Trunks.**—Drs. W. J. HARRIS and V. W. Low of London next contributed a paper on the importance of accurate muscular analysis in lesions of the brachial plexus and the treatment of Erb's palsy and infantile paralysis of the upper extremity by cross union of the nerve trunks. In this it was maintained that in man the deltoid, spinati, biceps, and supinator longus muscles were supplied almost, if not entirely, by the fifth cervical root. The importance of faradic stimulation of the nerve roots at the time of the operation was insisted on. Three cases of the treatment of the paralysis by cross union of nerve roots were described; in one of the cases immediate recovery of sensation was obtained after the operation and in the galvanic reactions distinct improvement resulted after six weeks. In one case, although the paralyzed muscles gave the reaction of degeneration through the skin, yet they reacted to faradism of the corresponding nerve trunk.

**Serum Therapy.**—Dr. R. LORD of London made some observations on the treatment of disease by antitoxins, toxins, vaccines, and other forms of serum therapy.

Dr. BERTRAND DAWSON of London argued for the isolation and standardization of the active principle of antitoxins.

Dr. E. LANCASTER of Swansea referred to cases of recovery from tetanus after the injection of antitanic serum.

*Thursday, July 30—Second Day.*

**The Medical Treatment of Gastric Ulcer.**—Dr. H. D. ROLLESTON of London opened this discussion. The general treatment, that of absolute physiological rest, although universally recommended, was not always rigorously car-

ried out. Many allowed sips of water, but water was absorbed from the intestine and had to be expelled from the stomach by peristaltic action. Nothing should be allowed in the stomach, but the mouth should be kept clean by a mouth wash which diminished the risk of infection of the stomach. Patients fed by the rectum frequently developed parotitis, and this might be attributed indirectly to dryness of the mouth. It was recommended that the rectum should be washed out daily with non-irritating antiseptic solutions. If enough water were given by the bowel nutrient enemata need not be given for a week. Diacetic acid was very common in persons who had been starved or had been treated by rectal feeding. Semisolid nutrient enemata were sometimes better than fluid. Drug treatment intended to bring about a cure was directed to increasing the bodily resistance or to removing any underlying cause. As soon as gastric irritation had subsided, iron should be given. In men potassium iodide should always be tried, as the ulcer was often syphilitic. Apart from perforation, the only complication requiring surgical treatment was repeated hemorrhage. Vomiting was an indication for absolute rest, but it might persist although nothing was given by the mouth; the vomiting might be reflex from the rectum, or due to sepsis. Hæmatemesis was to be treated by absolute rest and the hypodermic injection of morphine to calm anxiety. Adrenalin locally might also be of benefit in arresting hemorrhage. Ergot was contraindicated as it raised blood-pressure; digitalin and lead were also not to be given. Allusion was made to the use of citric acid when the coagulation time of the blood was short. Operative interference was justifiable in persistent pain, in persistent pyloric obstruction, and in repeated hæmatemesis.

Prof. R. SAUNDBY of Birmingham premised his remarks by saying that the diagnosis of gastric ulcer must be admitted to be imperfect. If a patient were vomiting seriously and had pain he should be put to bed and placed on a milk diet, and then gradually restored to a full diet. Later sulphate of iron and sulphate of magnesia were indicated. If recent hæmatemesis were present the patient should be fed by nutrient enemata alone for forty-eight hours, after which the milk and lime-water feeding might be commenced. Prolonged starvation and prolonged rectal feeding were to be deprecated; physiological rest to the stomach was not good. If pain persisted, alkalies were first to be tried on the supposition that it was due to hyperacidity, or if it were very bad, morphine might be given hypodermically. Drachm doses of olive oil by the mouth had sometimes seemed to relieve pain. He had had only one death in 200 cases of recognized gastric ulcer under treatment, and had never found the vomiting intractable. For hæmatemesis he usually applied an ice-bag to the epigastrium and gave morphine hypodermically; if persistent, the question of operative interference should be considered.

Dr. W. J. TYSON of Folkestone thought that every case of anæmia should be looked upon as a potential case of gastric ulcer.

Dr. H. W. KING of Chester insisted on the importance of good nursing in the treatment of gastric ulcer. He recommended rectal alimentation for six to seven days. Water should, he thought, be given freely by the mouth unless there was much vomiting or hæmatemesis. Washing out of the bowel should not frequently be had recourse to—not, for example, daily. Adrenalin used in one case did not seem to do much good.

Dr. W. COLLIER of Oxford referred only to the treatment of gastric ulcer in anæmic women. It was very rarely a fatal disease. Rectal feeding was chiefly of value from its mental influence. In recurrent hemorrhage morphine and the application of the ice-bag for short periods were indicated. For the relief of pain bismuth was of much value, but it should be given before food; large doses of alkali and cannabis indica were also of value.

Dr. F. D. BOYD of Edinburgh considered that cases of chronic ulcer should be operated on. He approved of withholding even water by the mouth. It was debatable whether the value of rectal feeding was commensurate with the discomfort it afforded. It might be continued while there was absence of gastric hyperæsthesia. Iron, as the citrate, might be given hypodermically. In view of operation it was to be remembered that the ulcer could not yet be localized. If the bleeding point could be found surgical aid was advisable, but he deprecated gastroenterostomy. He asked if there was really hyperacidity in gastric ulcer?

Dr. A. MCPHEDRAN of Toronto referred to the occurrence of hæmatemesis in patients without ulceration, and in these there was, he had observed, hyperacidity. In such he had found olive oil of benefit in diminishing the pain and hyperacidity. The question of operation for hæmatemesis was to be entertained with caution, chiefly because the hemorrhage was usually from a minute opening. He alluded to the value of operation for persistent pain, caused apparently by gastric adhesions.

Dr. T. D. GRIFFITHS, president of the association, said the object of its treatment was physiological rest, principally by rectal feeding. The guide in this was the state of the mouth, the tongue should be moist and the breath sweet. Absolutely nothing was to be given by the mouth. An antiseptic mouth wash might be used. In slight cases ten days of this treatment was usually sufficient. Then the diet must be gradually increased, as in feeding an infant, during a week or ten days. He would avoid the use of cane sugar. From four to six ounces of digested food may at first be given every four hours. In addition drinks of saline bland fluids might be given even to three or four pints a day. The bowel during rectal alimentation need not be washed out except every three or four days. There should be no flatulence allowed. If the rectum became irritable a little laudanum might be given by the rectum. From two to three weeks in bed should be sufficient in most cases. When relapse threatened, the treatment should be resumed.

Dr. BERTRAND DAWSON of London also alluded to the difficulty of diagnosis. He would feed by the rectum for one week. The mental good of nutrient enemata was perhaps equal to the physical. The harmfulness of withholding food altogether was perhaps exaggerated.

In acute hæmatemesis in addition to ordinary treatment he would give calcium chloride in rectal injection. Bleeding from the stomach was often from multiple points, and this seemed to contraindicate operation. Both ergot and adrenalin were, he considered, unsafe. An emergency operation for acute hæmatemesis was not to be recommended—the cases almost invariably yielded to medical treatment. Dr. W. Ewart of London contributed to the discussion a demonstration of an instrument for the continuous administration of nutrient enemata.

Dr. G. PARKER of Clifton had tried the administration of calcium chloride by the mouth with good effect, and insisted on giving a large amount of water daily by the bowel.

Dr. Rolleston, in reply, said he had found hyperacidity in some cases of gastric ulcer and had not found it in others.

Papers were read by Dr. E. LLOYD JONES of Cambridge on "The Physical Examination of the Chest," and by Dr. J. HADDON of Denholm "On Food and Fasting in the Treatment of Disease," in which he argued for the establishment of lectureships on dietetics in medical schools.

---

**Dysentery in South America.**—On the western side of South America dysentery is widely prevalent. In Ecuador it is common in the rainy season. In Peru it is endemic along the coasts, and is said by Hirsch to occur in the interior, at such elevations as 8,000 feet and even 13,000 feet above sea level. Dysentery is met with in all parts of Chile.—Clemow's "Geography of Disease."

## AMERICAN ORTHOPEDIC ASSOCIATION.

*Seventeenth Annual Meeting, Held in Washington, D. C., May 12, 13, and 14, 1903.*

**Special Report to the Medical Record.**

FIRST DAY—TUESDAY, MAY 12.

**President's Address.**—Dr. LOUIS A. WEIGEL of Rochester, N. Y., delivered this address. He spoke of the decadence of the family physician, and pointed out some of the reasons for this unfortunate state of affairs. While part of this was no doubt due to the growth of specialism, a good deal depended upon the lack of interest or careful observation of the general practitioner in certain lines of work. Specialists were useful, particularly if they had received sufficient general training before taking up their specialty, but in small communities, at least, the general practitioner was, and always would be, *the* doctor. The specialist would be the connecting link between the patient and the family doctor, and should serve as a buffer to prevent collisions between these two parties

**Excision of the Knee for Bony Ankylosis; Report of a Case.**—Dr. A. J. STEELE of St. Louis presented this report. He said that osteoclasis was rarely applicable in these cases, and, as a rule, cuneiform osteotomy was indicated, and could be practised with very satisfactory results. This was the treatment in the case reported in this paper. So large a piece of bone had to be removed that unfortunately it became necessary to sacrifice the femoral epiphysis, but the tibial epiphysis was spared. The limb, after straightening, was fastened by nails, and a fixative apparatus was applied. At no time after the operation was there any unfavorable symptom. The specimen showed ossific union of the three bones making up the joint. He had used ivory and bone pins in this operation, but had found them unsatisfactory, and hence, he preferred to use steel nails until sufficient callus had been thrown out. A well-fitted leather brace, fashioned over a plaster case, was subsequently used. The patient in this instance was a healthy boy, apparently without constitutional taint, tuberculous or otherwise, so that the trouble appeared to be purely a local one.

Dr. JOEL E. GOLDTHWAIT of Boston said that the point to be borne in mind was, that children's bones, where epiphyses were approximated, did not form a firm bony ankylosis as rapidly as they did later in life. He reported a series of cases allied to the one just reported. All of them had been treated by wedge-shaped exsection, and in all considerable difficulty had been experienced in maintaining a good circulation after the straightening of the leg. Apparently the vessels were bound down in cicatricial tissue, and it became necessary to flex the leg a little in order to secure a proper circulation. One of the patients had been transferred and had been attended by a general surgeon, and in this case the leg became gangrenous and amputation was required.

Dr. A. J. GILLETTE of St. Paul said that from Dr. Steele's paper one might perhaps infer that ankylosis of the knee-joint from tuberculosis was quite common; in reality he believed it to be quite rare. Since he had been using forcible correction he had not found a single case which could not be straightened in this without tenotomy.

**The Abuse of Flat-foot Supports.**—Dr. W. R. TOWNSEND of New York read this paper. He said that flat-foot was often confounded with osteitis of the ankle, metatarsalgia or a neuritis. When flat-foot did exist, it did not necessarily follow that a support should be applied. Extreme spasm or deformity or inflammatory conditions might be present, and the use of a support might do more harm than good. Another error was the application of supports which did not fit or fulfil the indications for treatment, or were so frail that they could not act as supports. In many cases the support was applied so far forward or backward that it was of no assistance in preventing deformity—indeed, deformity might be actually produced and disability caused by the use of such supports. Different cases required different treatment, hence no one support could possibly serve a good purpose in all cases of flat-foot. Temporary relief might be obtained, but not a cure where there was flat-foot, and the use of a defective shoe would often more than counteract the benefit which should be derived from a flat-foot support. The routine practice of treating these conditions by ready-made supports sold by those who had no accurate knowledge of the anatomical conditions to be treated, should be discouraged.

Dr. ROYAL WHITMAN of New York called attention to the fact that little children with pigeon-toes almost always had weak feet or knock-knee. It was common to take these children to a shoe store and have the shoes raised on the outer side, a practice which was very bad.

Dr. R. TUNSTALL TAYLOR of Baltimore remarked that he had recently seen a case in which the patient had been made distinctly worse by wearing a foot-plate made by an instrument-maker.

Dr. GOLDTHWAIT referred to a class of cases in which there was undoubted flat-foot, and yet which had exhibited no improvement in his hands under the use of flat-foot plates. These cases were instances of rigid or extreme valgus. Only within the past few months had he recognized these cases as talipes valgus instead of varus, and had treated them just as they would an obstinate valgus. The usual treatment had been to excise the scaphoid and shorten the inner side of the foot, after which the correction of the position was easy.

**The Surgical Pathology of Genu Varum and Genu Valgum.**—Dr. WALLACE BLANCHARD of Chicago presented this paper. He said that a case of genu varum usually showed three contributing curves which, in the order of their development were: (1) An exaggeration of the normal out-curve of the lower femur; (2) an out-bend of the upper part of the tibia, and (3) a distributed out-bend of the tibial shaft. The least amount of over-correction was required at the culminating point to give a straight and lengthened leg. In genu valgum the primary inward bend was usually in the upper part of the tibia, and the succeeding inward curve became distributed through the shaft of the tibia. The least over-correction was necessary at the apex of the deformity in the tibia. According to Renier, the operation of epiphysiolysis was applicable to children between seven and seventeen years of age, while Lorenz would employ it only in those between five and sixteen years of age. Dr. Blanchard said that he had tried the operation, following closely the directions laid down by Renier, but had only succeeded in overstretching the external hamstring and opening up the outer half of the joint, and the operations had been followed by considerable swelling and severe pain, so that he had not felt justified in further resorting to this very dubious procedure. In his opinion, rapid osteoclasis, by the method he had previously described, was a superior plan of treatment. In bow legs with three contributing curves, the apex of the most prominent part was usually selected for the operating point. He did not think epiphysiolysis was hardly worthy of consideration when compared with osteotomy or osteoclasis, and that the former operation presented somewhat greater risks, and the longer period of recovery should condemn it when osteoclasis was available.

**Mechanical versus Operative Treatment of Rachitic Deformities of the Lower Extremities; a Statistical Review.**—Dr. R. TUNSTALL TAYLOR of Baltimore presented this paper. He said that out of 109 cases they had had only two relapses and one of over-correction. The statistics seemed to him to point very clearly to the great superiority of the operative treatment. The author then presented a new osteoclast which he had devised. It worked on the lever principle. There was a T-brace, measuring twelve by thirty-six inches. Arising from the intersection of the arms and the "T" was an arched support holding the mechanism for working the lever.* The latter measured twenty-four inches in the

long arm and six inches in the short arm. Its action was very rapid, accurate, and effective.

Dr. AUGUST THORNDIKE of Boston was pleased with this instrument because it seemed to imitate more nearly the production of a fracture by natural processes than any other osteoclast hitherto invented.

Dr. JOHN RIDLON of Chicago said that this was a beautiful mechanical device, but he thought a round or elliptical bearing pad would act better than a flat one, and that with the present leather covering the skin would almost surely be badly lacerated.

Dr. HENRY LING TAYLOR of New York said that he made use of the Grattan osteoclast as modified by Drs. Phelps and Weigel, and with it difficulty was experienced in producing a fracture in close proximity to the joint. The inversion of the foot, occurring in nearly all cases of bow-legs, was apparently due to a twist in the shaft of the tibia; hence, in operating, one should take pains to manipulate the fragments until they were quite free, and then give the lower fragment a strong twist outward.

Dr. W. R. TOWNSEND said that he had seen this new osteoclast work, and was of the opinion that it was likely to supersede the clumsy and expensive Grattan instrument.

**The Treatment of Paralytic Talipes by Tendon-transplantation Supplemented by Other Operative Procedures.**—Dr. ROYAL WHITMAN of New York read this paper. He thought tendon-transplantation, in its original form, had not proved as effective as had been expected. The simplest and most important function of the foot was weight-bearing, and next in importance was plantar flexion; then came dorsal flexion, and, finally, abduction and adduction. The object of treatment was primarily to prevent deformity, because this was intimately connected with the function of the part. Tendon-transplantation was especially applicable in paralysis of the anterior leg group of muscles with lateral distortion, and yet even in this class recurrence of deformity was the rule rather than the exception. The most constant cause of failure with this treatment was the mechanical disadvantage at which the transferred muscle must do its work. If the deformity were of the varus type the foot should be placed in abduction. If the deformity were of the calcaneo-valgus or varus type the most useful operation was astragalectomy with backward displacement of the foot upon the leg, and the removal of the cartilaginous surfaces. A supplementary measure was the shortening of the elongated tendo Achillis. The attachment of transplanted tendons to those of the paralyzed muscles should be replaced by direct implantation as a point of selection. The effect of the transplantation should, wherever possible, be assured by doing accessory operations, such as arthrodesis of the mediotarsal joint, for the prevention of varus or valgus deformity and astragalectomy. The latter should be done in case of an immature ankle-joint.

Dr. GOLDTHWAIT said that tendon-transplantation frequently made it possible to discard a very clumsy brace and substitute a lighter one; exceptionally it was possible to discard all apparatus. Some of the most satisfactory functional results from this operation had been obtained by operations upon the thigh. He had been considerably perplexed by the formation along the sheath of the tendon in its original position of a cicatrix, which subsequently became organized and thus gave the tendon a double pull. This resulted in a considerable diversion of power.

**Acute Atrophy of Bones and Joints Following Comparatively Slight Injuries.**—Dr. JOEL E. GOLDTHWAIT presented this paper. He referred to cases of comparatively slight injuries followed by prolonged joint disability. There was usually, he said, a swelling of the part, but not very acute, there being an absence of great limitation of motion. These cases had yielded but slowly to treatment, and had left in some instances a permanent disability. Several cases were reported and elucidated by the exhibition of skiagraphic negatives. The cases had done well under treatment which did not involve complete fixation, but was founded on the view that the condition was chiefly one of atrophic disturbance. He thought the subject was one which should receive very serious study from orthopedic surgeons, for certainly many very careful surgeons, familiar with this aspect of the subject, would be disposed to make a diagnosis of hysteria. The *x*-ray showed general atrophy of the bones and joints of the affected part, and explained the permanent disability.

Dr. WHITMAN remarked that Wolff had been one of the first to demonstrate that the bones were living tissue. He saw no reason for invoking the action of the trophic nerves when it was just as easy to explain the condition on the ground that the bone itself had been injured.

Dr. STEWART L. MCCURDY of Pittsburg said that he had been interested in this subject for many years, having first had his attention directed to it by a case of general atrophy of the entire right arm as a result of injury. It should be remembered that the atrophy or trophic change was dependent not so much upon a lesion of the cerebrospinal as of the sympathetic system.

Dr. L. A. WEIGEL said that the condition was not one involving a whole extremity, but was an eccentric atrophy, which was in the internal structure and did not effect the contour of the bone at all. There was no way of making a positive diagnosis in these cases except by means of the *x*-ray. In one case in which he had made skiagraphs from time to time he could observe the progressive change. There was a peculiar cadaveric coldness of the affected part that was quite characteristic. This atrophy, it should be noted, did not confine itself to the seat of injury. In tuberculous conditions there was apt to be a more general softening.

**Early Operative Treatment of Tuberculous Osteitis of the Knee.**—Dr. BERNARD BARTOW of Buffalo was the author of this paper. He said that between protective treatment and excision of the knee there was commonly no middle course of treatment. The indication for excision should be invasion of the joint by the disease. An epiphyseal focus could often be detected before such joint involvement occurred. If such a focus were found by trephining the diseased tissues should be curetted away and the cavity treated with carbolic acid, iodine, or chloride of zinc. The operation should then be united by suture. Severe flexor contraction should be relieved by open division within the tendon sheaths, and while repair was taking place in the severed tendons the joint should be placed completely at rest, thus removing the disturbing influence of muscular tension. Fixation had not been required beyond six months in any case. It was not advisable to employ this procedure in cases showing impending involvement of the joint. Failure to arrest the tuberculous process in no way impaired the result to be expected from later excision.

SECOND DAY—WEDNESDAY, MAY 13.

**Some Points in the Treatment of Hip-joint Disease.**—Dr. GEORGE B. PACKARD of Denver read this paper. He said that he had never allowed complete weight-bearing as early as Lorenz recommended, yet he had been impressed with the retardation of growth resulting from lack of functional use. For some time he had been in the habit of employing prolonged fixation, but he had recently returned to the treatment taught him by the late Dr. C. Fayette Taylor, and which comprised the use of a long splint until the subsidence of tenderness and muscular spasm, and then the use of a walking splint. One should not lose sight of the advantage of massage and protected use after the acute stage. These children should have three substantial meals a day, each meal to be followed by a glass of milk and a raw egg. This was not so apt to cause gastric disturbance as when the eggs and milk were taken midway between the meals. Meat, fats, raw eggs, and

milk should be prominent elements in the dietary of tuberculous children. It was of the utmost importance that dietetics and hygiene should receive careful consideration.

**Observations on Hip Disease as Seen in Hospital Out-patients.**—Dr. Augustus Thorndike of Boston was the author of this paper. The cases made use of in this study were those in which the treatment had been commenced from nine to eleven years ago, and had been kept up for a reasonable length of time. The total number of cases was fifty-five, of which number seventeen had the disease in the right hip, thirty-six in the left, and two in both hips. The children varied in age from six months to twelve years at the time of first coming under treatment. The first five years of life furnished 51.7 per cent. of the cases; the second half of the first decade, 42.6 per cent., and the period between the ages of ten and twelve, 5.5 per cent. The favorite age for the development of the disease appeared to be between two and seven years. As an evidence of the widespread educational influence of the teachings of orthopedic surgeons it was stated that only five of the cases were brought to the hospital at a period greater than a year after the detection of the malady. The shortest duration of treatment was four years, and the longest was now over eleven years. In forty-nine out of the fifty-five cases some modification of the Taylor long traction splint was used. Prolonged recumbency in bed had never been employed, but the Bradford frame had been used in 53 per cent. of the cases for periods varying from one to eight weeks. Abscesses were present in 42 per cent. of the cases, and in 38 per cent. the abscesses were incised, curetted, and drained. Tuberculous sinuses persisted for many months after incision and drainage. The number of cases with abscess proved the disease to be of a severe type. The average shortening was one and one-third inches. Twenty-two of the cases had more than 22° of motion. Motion in abduction was impossible in fourteen, and was almost normal in eight cases. These statistics showed that even in an out-patient clinic and with poor home care certainly more than half of the cases had a fair walking gait. The results were a little below what had been achieved in some other hospitals in this country. Almost all of their cases were walking well when the real or apparent shortening was compensated for by a high sole.

**Hip Disease Considered with Special Reference to the Combined Treatment.**—Dr. R. Tunstall Taylor of Baltimore read this paper, which was supplementary to one presented last year. In that one he had dwelt upon the great value of the skiagraphic diagnosis, a method which he considered to be preferable to the use of tuberculin. He had discarded disinfection of the cavities by carbolic acid, having lost one case so treated from carbolic-acid poisoning. Formalin was now employed as a safer agent. Tuberculin should be discarded because it had been shown time and again that the characteristic reaction of tuberculosis, obtained with this agent, was also observed in syphilitics, lepers, and neurotic individuals. He would recommend tuberculin only when good *x*-ray negatives could not be obtained, or were inconclusive. To show the value of taking skiagraphs from time to time in order to study the progress of the disease, the speaker reported a series of cases, exhibiting the skiagraphs, and also two patients. He said that from the results so far obtained he should continue the use of the combined treatment in cases in which skiagraphs showed extensive caseation until he became convinced of his error. The patients were kept in bed for six or eight weeks with traction in abduction, and then wore a traction splint and high shoe for about one year. Lorenz had criticised the long period of traction as detrimental, and he was inclined to think that this criticism was deserved and that it would be well to make use much earlier of some form of convalescent apparatus. The *x*-ray would aid in determining the proper time for tentatively allowing functional use.

Dr. Bernard Bartow of Buffalo, speaking of the paper by Dr. Packard, said that his own experience was to the effect that with the best climatic conditions and constitutional treatment movement was no advantage, and that fixation, pure and simple, and as perfect as possible, was essential. He had also been interested in Dr. Taylor's statements regarding the length of treatment, and was of the opinion that the method advocated by him was ideal for almost any period of the disease. The more quickly a tuberculous focus was removed, the better the chance of arresting the process and securing good restoration of function.

Sir William Hingston of Montreal, Canada, said that he had long ago come to the conclusion that to keep a child for an indefinite period with extension was a mistake. In a great number of the traumatic cases—and most of them were traumatic—one could obtain a desirable result without resort to the knife. He was thoroughly in favor of early operating, but he did not quite see the advantage of the anterior incision over the one advocated and practised by the late Dr. L. A. Sayre and many others.

Dr. G. G. Davis of Philadelphia said that he had not infrequently trephined the head of the bone in cases of acute tuberculous inflammation, making six or eight small openings. By this means one was able to cut short the acute symptoms. However, in several instances in which he had carried out this treatment with apparent success the symptoms had reappeared, showing that operative procedures did not in themselves cure the affection or relieve the surgeon of the necessity of relying upon rest as a curative measure.

Dr. V. P. Gibney of New York said he believed it to be good practice in these cases to cut down upon the points of infiltration, squeeze out the contents, and treat the case as one would an abscess which had been aspirated, sewing up the wound without drainage and without the use of any chemicals. A skin-fitting plaster-of-Paris bandage should then be applied, and an ice-bag, and the child should be kept at rest for some days. He had known of a number of cases in which the night cries had been dreadful, and nothing had been accomplished by traction or fixation, yet almost magical relief had followed the treatment just outlined. If chemical agents were employed, or a more extensive operation were done, one was apt to get beyond the area of disease. The subsequent progress of the case could be followed by taking skiagraphs from time to time. This should be the guide as to the amount of traction to be used and the length of time traction should be kept up.

Dr. Newton M. Shaffer of New York pointed out that the initial limp was the danger signal, and throughout the entire course of the disease the inability of the patient to bear the weight of the body upon the affected joint was clearly marked. When the patient had sufficiently recovered to show a disposition to bear his weight upon the affected limb, the surgeon was called upon to discriminate between the disability due to disease and that induced by the prolonged use of apparatus. Weight-bearing was the test of whether or not it was safe to leave off the apparatus. He would rather err on the side of using an apparatus too long than not long enough.

Dr. Clarence L. Starr of Toronto said that two or three years ago he had advocated before this society the practice of resorting to early curettage in tuberculous disease, and following this by swabbing out the cavity with pure carbolic acid, and he had not observed carbolic-acid poisoning in any of his cases. He was opposed, however, to the method of first using the carbolic acid and following this with alcohol, for the acid formed a wall of coagulum against absorption, and this was dissolved away by the alcohol, thus distinctly favoring the absorption of the carbolic acid. He had met with no such large proportion of cases with discharging sinuses as had been reported by Dr. Thorndike. When an abscess appeared

to be progressing the case was sent to hospital, thoroughly curetted and closed up, and, after a certain length of time, the patient was returned to the out-patient department.

Dr. GOLDTHWAIT remarked that the distinctive feature of the treatment advocated by Dr. Taylor was embodied in the use of the word "combined."

Dr. E. H. BRADFORD of Boston said that the difference in the proportion of cases with discharging sinuses in Boston and in Toronto could probably be explained by the difference in condition of the poor patients seeking treatment. The objection to Dr. Taylor's suggestion that when there was much detritus the surgeon should cut down upon and remove it was, that the hip-joint could not be treated the same as the knee or ankle. Moreover, the *x*-ray did not constitute a reliable guide as to the limits of the disease, as has been approved by experiments conducted in the pathological department of the Harvard Medical School.

Dr. B. S. MCKENSIE of Toronto said that while Dr. Taylor was right, in a measure, he was afraid he would overstep the bounds of prudence. Mention was made of the excellent results obtained in his city in the treatment of the orthopedic hospital patients in tents all the year round.

Dr. JOHN RIDLON narrated one very difficult case to show that it was not always possible to cure these cases or get such good results as had been reported by Dr. Taylor.

Dr. G. G. DAVIS agreed with Dr. Bradford as to the unreliability of the *x*-ray in showing the disease and its extent.

Dr. L. A. WEIGEL exhibited a picture which showed that bone atrophy at an early stage, and long before it was possible to attribute it to non-use.

Dr. Taylor, in closing the discussion, said that the anterior incision was employed in order to do as little damage as possible to the muscular structures The incision passed through the inter-muscular septum down to the capsule. He certainly did go a little beyond the diseased area, but trusted to the disinfectants to complete the cure.

**The Correction of Deformity at the Hip the Result of Disease; a Study of the Best Methods and Best Positions.**—Dr. V. P. GIBNEY of New York read a paper with this title. He said that experience had led him and many others to believe that the Gant operation was the safest and most effective operation yet devised for the cases in which it was indicated. While a longer limb could be obtained by centric correction, the procedure was not alway devoid of risk. It was unsafe to employ forcible correction when sinuses led down to the joint. It was true that there were some relapses after subtrochanteric osteotomy, but they occurred about as frequently after forcible correction through the joint. Possibly Lorenz obtained better results because of his prolonged uses of plaster of Paris. The claim had been made that the breaking up of the focus in which a reparative process was going on, by means of forcible correction was often responsible for the development of tuberculous meningitis, yet the available statistics did not prove any direct connection between the two. He would earnestly advise subcutaneous osteotomy as well as subcutaneous tenotomy. In conclusion, he expressed the opinion that the ability to sit comfortably should be sacrificed to the ability to stand and walk erect.

Dr. A. J. STEELE of St. Louis said that his own experience went to show that there was danger of tuberculous meningitis if extreme force were used in these cases. An illustrative case was cited.

Dr. JOHN RIDLON placed on record five cases on which he had operated after Professor Lorenz's visit last fall to Chicago. In all of the cases the deformity had remained corrected, and to his amazement there was motion to the extent of 5 or 10°

Dr. J. E. GOLDTHWAIT placed on record a series of sixteen cases, for the most part adults, which had been operated upon during the past winter, together with photographs of some of the cases.

Dr. N. M. SHAFFER said that while he was open to conviction regarding the propriety of performing forcible correction in advanced cases, he had not yet been convinced because he had seen so many disastrous results.

Dr. JOSEPH KURTZ of Los Angeles spoke in favor of doing osteotomy by the open method, claiming that there was no reason to fear infection.

Dr. Gibney replied that while theoretically there should be no reason to fear infection, nevertheless the fact remained that even surgeons most skilled in aseptic technique occasionally encountered infection.

**The Forcible Reposition of Congenital Luxation of the Hip.**—Dr. GWILYM G. DAVIS of Philadelphia was the author of this paper. He said that while many of the severe injuries reported from forcible reposition had occurred in older patients, they were not by any means confined to them. To call a method "bloodless" which produced hæmatomata extending from the middle of the thigh below to the umbilicus above certainly savored of sophistry. He would suggest that the tendons of the adductor muscles be cut subcutaneously, and thus considerable traumatism at this point be avoided. It seemed to him unnecessary to resort to forcible movements in all directions as a routine practice to loosen up the joint; it was not improbable that they tended to increase the functional disability and the tendency to displacement. Violent tractions for immediate replacement should be abandoned, for, everything that could be gained in this way could be obtained without danger by weight traction made in bed for a certain length of time. The method he recommended was practically that of Paci, the circumduction method of reducing luxations. The thigh was flexed upon the abdomen, followed by downward pressure upon the knee with abduction, external rotation and extension. Pressure was made upon the trochanter posteriorly while the limb was carefully extended. Abduction was maintained subsequently sufficiently to prevent the escape of the head from its new position. If the adductor muscles prevented the downward abduction they could be tenotomized, but it was not always necessary. Rather than to employ great force he believed it to be better to incise and clear the way for the head of the bone to enter the acetabulum.

**Congenital Dislocation of the Hip; Report of a Case of Bloodless Reposition Followed by Death, with an Analysis of Twenty-three Cases in Process of Treatment.**—Drs. H. AUGUSTUS WILSON and J. TORRANCE RUGH of Philadelphia presented this report. The patient was a girl of seven years with a double congenital dislocation of the hip. She was in fair condition, and the radiograph indicated that the conditions were favorable for replacement. The child was slightly rachitic. Reduction by the Lorenz bloodless method was undertaken at the Jefferson Medical College Hospital on March 18, 1903, at 11 A.M. All associated in this case were intimately connected with the eight cases reduced by Lorenz himself on December 11 and 12. The fifth and sixth hips reduced by Lorenz were extremely difficult, but finally yielded to his experienced and skilful manipulations. Thirteen hips were subsequently reduced at the hospital, and two outside, making a total of twenty-three hips. There were twelve girls and five boys; six were double and eleven single. Of the single ones, eight were right and three left. The youngest patient was twenty months; six were under two years; two were between two and three years old; five were between three and four years; five were between six and seven years; three were between eight and nine years, and two were ten years old. The case under discussion had been under treatment elsewhere since the age of two years up to within a few days of the operation by the bloodless method. Very great difficulty was

encountered in reduction, far greater than in a boy of ten years with a double dislocation. Complete, satisfactory reposition could not be accomplished. Fixation by plaster of Paris in the "frog position" was done with the expectation of a cutting operation at a later day. The anæsthesia was maintained for one hour and twenty minutes, and 3½ ounces of ether were consumed. The little patient became completely conscious after the operation, but after a time mild delirium developed, which was followed by collapse and death in twenty-two hours. The post-mortem examination was made by Dr. W. M. L. Coplin. A long and large ligamentum teres was found, which more than filled the acetabulum, and which prevented the reduction. The articulating surface of the head of the femur rested on the posterior and upper edge of the acetabulum. The capsule was elongated and thick. There was a fracture of the neck of the femur, one of the body of the ischium and one of the ascending ramus of the ischium. The ends of the bones were all in close apposition. In addition to these findings there were acute catarrhal bronchitis, acute catarrhal pneumonia and acute, diffuse hemorrhagic nephritis.

**The Resistance of Tissues as a Factor in the Manual Reduction of Congenital Hip Dislocations.**—Dr. E. H. Bradford of Boston presented this paper, which was based on observations in the anatomical department of the Harvard Medical School, and also upon clinical observations at the Children's Hospital. He declared that Lorenz's visit to Boston had taught him a number of new and important details. He was convinced that, in the treatment of congenital dislocation of the hip within the ages of three and six, Lorenz's method was correct and satisfactory. He had come to the conclusion that the resistance offered by the capsule was less than that offered by the muscles and their tendons. The chief resistance was from the strong tendon of the adductor magnus. The resistance to pulling down the head came from the hamstring group and the long tendon of the adductor magnus and the iliotibial band. These resistance tissues could be readily overcome by small tenotomies done at a distance from the hip. In the lighter cases, *i.e.* very young children, manual manipulations by the Lorenz method were sufficient. In the resistant cases mechanical force properly applied, so as to pull upon and adduct the limb, and also act directly upon the capsule, was of assistance. Where the tendon of the adductor magnus was so strong that an immoderate amount of force was needed, it would seem advisable to divide the chief resisting tissue rather than incur the danger of fracturing the femur or severely bruising the tissues. The division of the tendon could be done either before the operation or at the same time. The speaker said that Lorenz had refused to operate upon a girl of nine in the hospital with double congenital dislocation, because of her age. Dr. Bradford had subsequently cut down upon the parts, and after freeing the capsule, had found it impossible to bring the head down sufficiently. This had led him to an anatomical study, carried out with the aid of Professor Dwight. It had been supposed that the group of adductor muscles felt superficially were the chief obstacles to reduction. It was found that the lower fibers of the adductor magnus were collected in a strong tendon, but that a portion which was not inserted was situated near Hunter's canal. This tendon, which was an extremely strong one, could be neither seen nor felt without dissection. This fact showed that by a small incision and a division of this tendon, three-fourths of the adductor magnus could be thrown out of commission. These anatomical facts having been demonstrated by numerous dissections, the principles were put in practice upon certain children. One trouble with all manual correction was the difficulty of holding the pelvis. A lawyer in Boston had devised an instrument by which it had been found possible on two cadavers to dislocate the head of the femur downward. The apparatus had also been tried on children of thirteen, nine, and six years of age respectively, and in these cases the reduction was made very much more easily than by the manual manipulation, and caused the patients much less discomfort. The torsion of the femur was found to be the chief factor in transposition.

**Peripheral Palsies Following Manual Replacement of the Congenitally Dislocated Hip.**—Dr. Henry Ling Taylor of New York was the author of this paper. He said that one of the chief dangers of the Lorenz operation was that those who were not well acquainted with it might think it was easy of performance. He felt very grateful to Lorenz for the very frank way in which he had answered all the questions put to him. Having followed a number of the cases operated upon by Lorenz's method, he had been struck by the fact that the children did not get up and walk in every case within a few days or weeks as was desirable they should do. Examination of these cases showed a complete loss of power in the quadriceps muscle, and, therefore, of extension at the knee. It was found then that Lorenz had commented upon this fact in his book. Further inquiry showed nine cases of peripheral palsy of the quadriceps muscle. These cases had been examined from time to time since then, and all had either completely recovered or were recovering from this palsy without any treatment. Only two of these patients were over six years of age, a fact which did not agree with the conclusions of Lorenz. He had found two cases of palsy in the sciatic distribution, one being a patient ten years old, and the other thirteen. The first of these had completely recovered, and the other had nearly done so.

Dr. Roswell Park of Buffalo said that after listening to these papers he had been impressed with the folly of calling this a bloodless method, and he did not believe it was safe to break bones and tear tissues so indiscriminately.

Dr. James E. Moore of Minneapolis said that with all honor to the method and to those who had brought it to a wonderful state of perfection, he felt that there were certain attendant dangers. It seemed to him rational to believe that there were certain cases in which operative treatment would offer better chances for the patient. The so-called bloodless method touched a chord of popular sympathy by reason of its name, but he could not help feeling with Dr. Park that this operation often caused a much greater loss of blood than a clean cutting operation in the hands of an expert surgeon.

Dr. V. P. Gibney of New York said that he quite agreed with many of the remarks that had been made to the effect that this method was one fraught with a good deal of danger.

Dr. Newton M. Shaffer of New York said that he wished to express his great appreciation of Lorenz's visit and his efforts in this country, for they had been of immense benefit to orthopedic surgery. Dr. Lorenz had operated at his clinic, and in every instance had been prepared to do a cutting operation if it seemed to him to be indicated; hence it could not be truthfully said that he was always a "bloodless" surgeon. Personally, he did not regard the Lorenz operation as any more brutal than osteoclasis. It was greatly to be regretted that Lorenz was unable to be present at this time and participate in this discussion as he had expected to do.

Dr. George B. Packard of Denver exhibited some skiagraphs of cases upon which Dr. Lorenz had operated in Denver. In one of the six cases, that of a child of nine years, the bloodless operation was attempted, but because of the tearing of the subcutaneous tissues the operation was abandoned and the limb was put up in an abducted position. Two of the four skiagraphs showed the hip to be in perfect position; the other two skiagraphs showed anterior transposition.

Dr. John Ridlon said that he had seen a good deal of the work done by Lorenz in Chicago, and he wished to say

that he thoroughly believed this was the best single operation known for the treatment of the condition under discussion. He had notes, though not final ones, of twenty-one cases upon which Lorenz had operated, and of twenty-six cases upon which he had refused to operate, or a total of forty-seven cases. Of the operative cases, he failed to replace the hip in four; in one a fracture of the neck of the femur occurred; in one there was a fracture of the shaft of the femur, thus making six cases in which the replacement was not secured. In one of these cases, but not one of those in which fracture occurred, paralysis of the sciatic group resulted, and had not yet entirely disappeared. In one instance in which the replacement was effected, the perineum was torn. Dr. Ridlon said he had uncovered four hips upon which Lorenz had operated. The first was a child of four, and the hip was found in anterior transposition and the joint quite loose. In another child of four the hip was in anterior transposition and the joint firm. In the next case, a bilateral one, one hip was either in the socket or very slightly in front of it, while the other hip was the seat of a fracture of the femoral neck, and the head of the bone could be felt lying on a level with the greater trochanter and to the posterior and outer side of it. This gave a total of ten cases in which the final results were known out of the twenty-one cases upon which Lorenz had operated. All of the cases would be reported upon in detail at some future time. Three cases had been heard from, but not seen by him. One of these was said to be in good position; one was said to be in anterior position with the head beneath the femoral artery and nerve; in the third, Dr. Davis reported that the head of the femur had at once slipped out of the position in which Lorenz had placed it, but could be easily replaced in the same position

Dr. J. E. Goldthwait of Boston said that all who had been associated with Lorenz must have been impressed with the number of cases which he had considered inoperable—cases in which the children were too old or had too much deformity. It seemed to him that the discussion so far had only named facts and conditions which had already been described by Lorenz in his book.

Dr. B. S. McKensie of Toronto remarked that Lorenz had not claimed to present a perfected operation, and such claims as he had made had been put forward modestly and very unostentatiously. Lorenz had made the statement in a New York clinic that he thought in cases of double congenital dislocation a successful result should be obtained by him in 25 per cent., and that a successful result should be secured in about 50 per cent. of the single cases. This was very different from the view taken by the laity with regard to Lorenz's method. Moreover, those who saw Lorenz operate did not observe the exercise of any such remarkable strength as the papers pictured him as using.

Dr. Arthur J. Gillette of Minneapolis remarked that the laity and many of the profession seemed to lose sight of the fact that congenital dislocation of the hip was not always as terribly disabling as it was described as being, and that many of these persons did quite well if left untreated.

Dr. Leonard W. Ely of New York thought orthopedic surgeons were generally agreed that this condition gave rise to much disability, that it should be treated, and that the Lorenz operation, though by no means free from danger, was the best yet devised.

Dr. DeForest Willard of Philadelphia said that he had done the Lorenz operation before Lorenz's visit with indifferent results, but that since that time he had been using more force and with better results. Both clinical observation, and *x*-ray examination, however, had shown in every case not only a defective acetabulum but a defective femoral head and neck, and he felt sure, therefore, that a considerable number of these cases would relapse within a year after the child had begun to walk about. We should not allow the term "bloodless" to be applied to this operation, for a torn muscle bled far more profusely than a clean incision with a tenotomy. He predicted that in the future surgeons would divide the adductors with a knife in addition to doing the manipulative operation. He was inclined to think that when the head of the femur had remained on the dorsum of the ilium for twelve years it would do more harm than good to throw it into the anterior position; personally, he would, at the present time, be disinclined to throw the head forward in a patient over eight years of age.

Dr. A. J. Steele of St. Louis mentioned the case of a child of seven years upon whom Lorenz had refused to operate. Subsequently, by prolonged traction with division of the adductors, and by the use of screw power before operation, it had been found possible to reduce both hips.

Sir William Hingston of Montreal said that he had never before listened to a discussion characterized by so much fairness, clearness, and impartiality. Lorenz was not upon trial; it was his method, and the discussion on the latter had all been in the interests of the little patients. It was fortunate for these little sufferers all over the world that Lorenz had come to America, for the subject had been approached without previous prejudice, and in a short time it would be presented to the world entirely freed from error.

Dr. Clarence L. Starr of Toronto called attention to a case in which the ligamentum teres had proved an obstacle to reduction.

Dr. Joseph Kurtz of Los Angeles said that there was still another obstacle to reduction that had not been referred to, *i. e.* the elongated capsule. Lorenz overcame this by long-continued abduction and adduction.

Dr. G. G. Davis said that he did not think enough stress had been laid upon the use of continuous traction. Ultimately some of these cases would be treated by a cutting operation.

Dr. H. Augustus Wilson said that the notoriety attendant upon the visit of Lorenz to America had served to call the attention of general practitioners to these conditions, and the result would be that many of these cases would, in the future, be reduced at a time when this could be properly done.

Dr. E. H. Bradford, in closing the discussion, said that he had found the ligamentum teres present in quite a percentage of the young children. Some years ago he had exhibited a specimen showing the folding in of the capsule, and had at that time expressed the opinion that this was the chief obstacle to reduction. He was now inclined to think that he had exaggerated the importance of this condition as an obstacle to reduction, and this view was shared by Dr. Royal Whitman. The Lorenz operation was a very serious operation even in a small child, and he desired to insist that it should only be undertaken by one fully competent to do it.

THIRD DAY—THURSDAY, MAY 14.

**A Treatment of Osteitis Deformans and Osteoarthritis.**—Dr. Frank E. Peckham of Providence presented this paper, reporting four cases of osteitis deformans and one of osteoarthritis treated by a superficial cauterization of the skin in the vicinity of the diseased area. The actual cautery was used once a month, and midway between these applications a small blistering plaster of cantharides was applied over that portion of the spine corresponding to the nerve center for the part involved. Three of the cases were apparently well, and one was rapidly improving. One case showed slight improvement, but abandoned the treatment because of its harshness.

Dr. Goldthwait said that it was well known that counterirritation over the seat of the active process would give relief, and that there might be a long period of quiescence before the disease again became progressive. He was disposed to doubt the correctness of the diagnosis in the case of osteitis of the hip, because in such cases rotation was a mechanical impossibility, and yet the reader of the paper

had stated that there was no limitation of rotation. It was probably a case of iliopsoas bursitis. Osteoarthritis of the shoulder was associated with pain over the anterior part of the humerus at the attachment of the anterior part of the capsule, and hyperextension of the shoulder always caused pain. Any form of counterirritation which would improve the circulation of the part would give relief.

Dr. Peckham replied that if the case had been one of iliofemoral bursa of such long standing it would not have been cured spontaneously in the manner described.

**An Unusual Case of Pott's Abscess.**—Dr. STEWART LEROY MCCURDY of Pittsburg reported this case. The essential point was that the abscess was incised below Poupart's ligament, and that subsequent irrigations proved that there was a direct communication with the air passages.

**Bone Wiring for Recent and Ununited Fractures, with Report of Cases.**—Dr. MCCURDY also read this paper. He said that in cases of six months' duration or longer one must cut down upon the fragments and make use of various methods of uniting the bones. It had been his practice for some time to leave the bones down in their normal position while wiring them, thus preserving their nutrition. When they were brought out of the wound in order to facilitate wiring the periosteum must be damaged, and the nutrition of the fragments impaired, so that necrosis of the ends was liable to occur. The method he employed consisted in making an incision over the fracture sufficiently long to permit of the resection of the ends of the bones, but they should not be sawed off unless they overlapped or were uneven. The wound should be kept open during this process by means of shoe-horn retractors. He favored the introduction of the wires in such a way as to disturb the medullary canal as little as possible, and, hence, the wires were not passed completely through the bones. He made use of iron broom-wire instead of silver wire, because the former metal only was a normal element of the body. The blackening of the silver wire showed that this metal was gradually converted into a sulphide. In one case, in which silver wire ulcerated through in a short time, iron wire was then inserted, and a skiagraph, taken after a period of five years, showed that the iron wire had remained *in situ* and had given rise to no irritation. Dr. McCurdy also presented an instrument for use in cutting the ends of the bone; he also described a method of anchoring bone fragments to external bridge work to hold them in place during repair.

**A Further Study of the Mechanics of Rotary Lateral Curvature of the Spine.**—Dr. R. W. LOVETT of Boston presented this paper. He said that he had been able to show by experiment that neither the articular processes nor the different elasticity of the two elements of the spine was necessary for the production of torsion, but that such torsion took place in the column of vertebral bodies alone, and that this column, therefore, must be considered mechanically as a straight flexible rod. Bending in the antero-posterior plane was found to cause side displacement. It could not be bent to one side without twisting, nor could it be rotated or twisted without acquiring a lateral curvature. A left lateral curve was acquired by twisting to the right, and the reverse by twisting to the left. This curve was constant and marked. If the twisting were made during full flexion, the lateral curve instead of being in the dorso-lumbar region would be in the cervical region. In total left scoliosis there were three conditions, so far as the shoulder girdle was concerned, which caused an obliquity with regard to the pelvis: (1) A total lateral curve to the left, occurring in a flexed position of the spine; (2) a lateral curve to the left, occurring in an extended position of the spine, and (3) a lateral curve, occurring as a result of a twist. These conditions could be identified clinically without difficulty. The therapeutic application of torsion was, therefore, plain, but it was not possible as yet to say what was the therapeutic value in cases having fixed curves. The torsion, as he had given it, had been both active and passive.

**Treatment of Lateral Curvature of the Spine.**—Dr. GWILYM G. DAVIS of Philadelphia read this paper. The treatment advocated by the author was: (1) To confine the patient to bed a large part of the time with the object of overcoming body weight; (2) while in bed to employ weight extension to head and lateral pressure by bands and other means to assist in straightening the spine by position; (3) to have the patient rise daily and take suitable gymnastic exercises, and (4) in walking cases to make use of exercises, and if the deformity were marked, to use braces also.

**A Consideration of the Proper Arrangement of the Clothing in Growing Children with Reference to the Prevention of Faulty Attitudes.**—Dr. J. E. GOLDTHWAIT of Boston was the author of this paper. He said that in examining these children he had been deeply impressed with the amount of weight carried on the shoulders. The stocking straps were almost invariably attached to the waist, and the child was, therefore, carrying on each shoulder all the time a weight equivalent to from three to five pounds. Moreover this weight was upon the movable part of the shoulder. The normal position, with the shoulders square, could not be long maintained with the clothing so supported, and this consequently led to stoop shoulder, flattening of the chest, protrusion of the abdomen and of the head, all of which must result in the production of muscle strain, particularly on the spinal muscles, weakness and, frequently, in lateral curvature. It was a very different matter when this weight was borne on the base of the neck just as was done in the adult male with the suspenders properly applied. When the weight was so applied, the shoulders being left free, the element of muscle strain already referred to was eliminated, and personal comfort was promoted.

**The Scoliotone, a Machine for Elongating the Spine and Lessening the Rotation in Lateral Curvature.**—Dr. COMPTON RIELY of Baltimore presented this apparatus and paper by invitation. He said that a fact, which had not been commonly mentioned in the literature, was that almost invariably in these cases there was an asymmetry of the two sides of the pelvis. He had found that the anterior superior spine was usually from one-half to three-quarters of an inch higher on the convex side. The author called attention to the importance of obliterating mechanically the element of lordosis as a preliminary to the lessening of the lateral and rotary deformities, and cited in confirmation the advantage of Swedish corrective exercises and in the use of casts for corrective jackets. In the machine, called the scoliotone, which he presented, the direction of the correcting force was adaptable equally to the lateral deviation and rotation, or chiefly to one element or the other. The machine consists of a quadrilateral frame of gaspiping, a stand and a lever for raising weights.

**Home Apparatus for Forcible Correction of Lateral Curvature.**—Dr. R. W. LOVETT of Boston exhibited a cheap and efficient apparatus suitable for use at home by dispensary patients.

Dr. A. B. JUDSON of New York, in opening the discussion, said that a brace applied to produce anteroposterior pressure would be useful in treatment, although not practically efficient for absolute reduction of the deformity A column which bent anteroposteriorly and at the same time laterally, might be said to have not two curves but rather one curve partaking of anterior and lateral qualities —in other words, a simple curve produced by a force the resultant of two forces, one acting on the anteroposterior, and the other on the lateral curve. This was not necessarily attended with rotation, a new movement due to something extrinsic.

Dr. B. S. McKensie thought the greatest possible force

could be applied by suspending the weight entirely by the spine, and applying a lateral force by means of a girdle around the body until the latter was drawn to an oblique position of 45° or 50°.

Dr. N. M. SHAFFER said he had devised, and hoped very soon to put in practice, an operation for preventing further increase in the curve by producing a synostosis in the contiguous articular processes.

**Breaking Down of the Foot in Trained Nurses: A Series of 500 Observations on Normal and Disabled Feet.**—Dr. R. W. LOVETT of Boston presented a paper on this subject, based on 500 consecutive observations on the nurses entering a large general hospital. For a period of eight years he had had an opportunity of observing and recording any static trouble occurring while these nurses were in the training school, having from 100 to 140 nurses constantly under observation for two years or more after the first examination. It was found that the foot broke down in about 60 per cent. in the spring, or about two months after coming to the school. It was found necessary for the severer cases to go to bed, but the milder ones could be successfully treated by the use of felt pads and plates. In estimating the probable resisting power of the feet the only element that he had found of practical value was the bearing surface as seen through glass. A smaller proportion of those feet broke down which showed a broad bearing surface as compared with those in which the weight was borne on two "islands." He concluded that this kind of breaking down was more associated with general causes than with any special structure of the foot, and that the use of a good boot and proper supervision seemed markedly to diminish the amount of trouble.

**Officers Elected.**—*President*, Dr. Reginald H. Sayre of New York; *First Vice-President*, Dr. Joel E. Goldthwait of Boston; *Second Vice-President*, Dr Gwilym G. Davis of Philadelphia; *Secretary*, Dr. John Ridlon of Chicago; *Treasurer*, Dr. E. G. Brackett of Boston.

**Place of Meeting.**—The next annual meeting will be held at Atlantic City at the time of the meeting of the American Medical Association.

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 8, 1903:

| | Cases. | Deaths |
|---|---|---|
| Measles | 184 | 7 |
| Diphtheria and croup | 288 | 22 |
| Scarlet fever | 106 | 13 |
| Smallpox | ... | ... |
| Varicella | 14 | ... |
| Tuberculosis | 250 | 162 |
| Typhoid fever | 89 | 12 |
| Cerebrospinal meningitis | 5 | ... |

**Dearth of Physicians in Austria.**—The Medical Congress recently held in Vienna revealed a sorry, and at the same time anomalous, condition of affairs in the Austrian Empire. Twenty thousand committees, or 86 per cent. of all, are so poor that they cannot afford regular physicians, and 30 per cent. of the dead (in Galicia, 75 per cent.) are buried without medical certificate. Yet, while there is such need of doctors, the number of medical students is decreasing at a surprising rate. Of every 1,000 students in the Austrian universities this year, only 132 are in the medical departments. The total number of medical students is only 2,120 as against 5,277 in 1888-89—a decrease of about 60 per cent. in a little over a decade—and the decrease is likely to continue. At the Congress referred to, Dr. Wichmann earnestly warned all young men against choosing the profession of medicine, which he declared the Government had practically killed by its faulty laws in favor of the laboring man. Other speakers dwelt on the same point. They were not opposed to compulsory insurance against illness as such, but to the manner in which it is managed and to the abuses to which it has given rise, and which call for prompt remedies. From the country committees good physicians have long been excluded, because they cannot be supported there, and now that already one-third of the Viennese are taken from private practice by the Krankenverscherung and its underpaid employees, the outlook in the city becomes hopeless, too. Quackery naturally increases under such circumstances, and the medical man's resources are further cut off by the fact that, thanks to his own hygienic reforms, the number of cases of illness is little more than one-half of what it was twenty years ago.—*The Evening Post.*

**Saline Injections.**—The Berlin correspondent of the *Lancet*, reports that, at the German Surgical Congress, held from June 3 to 6, Professor Küttner of Tubingen said that he had made experiments for the purpose of ascertaining whether solutions other than salt-solutions could be used for intravenous injection; he had not, however, obtained any result of importance. He had found that animals which had been bled nearly to death were benefited by the administration of oxygen, and he demonstrated an apparatus by means of which the intravenous injection of saline solution and the giving of oxygen could be combined.

**Health Report.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended August 8, 1903:

### CASE OF SPLENOMEDULLARY LEUKÆMIA SUCCESSFULLY TREATED BY THE USE OF THE RÖNTGEN RAY.

BY NICHOLAS SENN, M.D.,
CHICAGO, ILL.

PROFESSOR OF SURGERY, RUSH MEDICAL COLLEGE; SURGEON-IN-CHIEF, ST. JOSEPH'S HOSPITAL; ATTENDING SURGEON, PRESBYTERIAN HOSPITAL.

IN the *New York Medical Journal* for April 25, 1903, I reported two cases of pseudoleukæmia that recovered under the *x*-ray treatment and have continued in excellent health since. Not long after this favorable experience with this new therapeutic resource, a typical case of splenomedullary leukæmia entered my surgical clinic in the expectation that I would condescend to remove the enormously enlarged spleen.

The patient is a foreign-born Jewess, twenty-nine years of age, married, and resides at present at Pittsburgh, Pa. Family history does not show any predisposition to malignant or chronic infectious diseases. Parents are both living and in good health, with the exception that her father has been the subject of a chronic affection of the middle ear, which has resulted in partial deafness, and at present complains of symptoms indicative of prostatic enlargement. Of her ten brothers, five died during childhood from unknown causes, the others are in vigorous health. She passed through the usual diseases of childhood —mumps, measles, and whooping-cough. When twelve years of age, the cervical glands became enlarged, some of them to the size of a filbert. These swellings were at first hard, but later softened when they were incised by a physician. The discharge of yellowish white pus continued for some time, when it ceased and the abscesses healed, leaving as many white atrophic scars. About the same time a chronic otitis media developed on both sides, which eventually led to perforation of the membrana tympani. There has been a discharge from the ears since that time and impairment of hearing. Several small ulcers of the right leg made their appearance about the same time, four inches below the knee. These ulcers were slow in healing but left no permanent ill results. Menstruation, of the twenty-eight-day type, appeared at the age of twelve years. She married at the age of seventeen years, and is the mother of five healthy children, all girls. No miscarriages or pelvic complications. With the beginning of the present illness menstruation was suspended. About fourteen months ago the patient became conscious of an increasing weakness, which became particularly noticeable on the slightest exertion and in the morning on leaving the bed. Three months later she discovered that the abdomen had become greatly enlarged. She then consulted a physician, who informed her that she was in the ninth month of pregnancy. The abdomen continued to increase in size gradually until the present time.

One year ago she began to experience a sharp pain at varying intervals in the left hypochondriac region, attended by a sense of fulness and weight in the same locality. This was soon followed by a dull, aching pain in the lower end of the sternum and the epiphyseal extremities of the large long bones. She has been subject to attacks of severe occipital headache since early childhood, but these attacks have been more severe since the commencement of the present illness, and at the present time the pain is almost constant. No epistaxis or hemorrhage from any of the mucous surfaces.

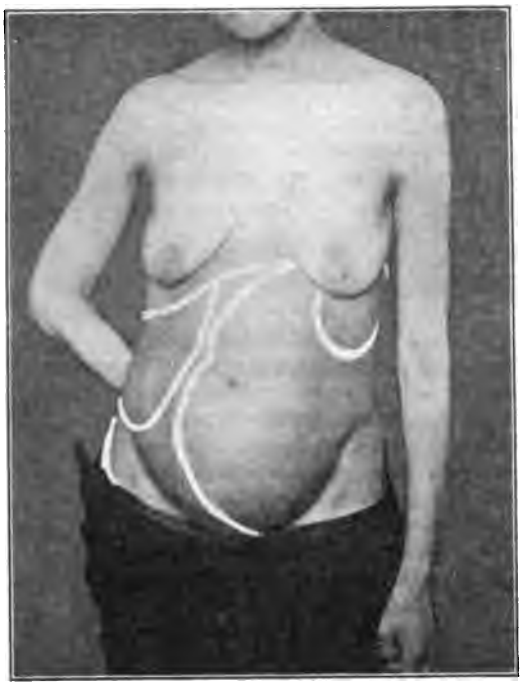
Two months ago she applied to one of the hospitals in Pittsburgh for relief, where, after examination, she was informed that her case was hopel ss and that she had but a short time to live.

The patient was admitted to the Presbyterian Hospital, Chicago, January 1, 1903, and was assigned to my service. The patient is a woman above average height, somewhat emaciated and profoundly anæmic. The face is not only very pale, but the pallor is combined with a yellowish tinge. Ophthalmoscopic examination negative. Scanty serous discharge from ears. Both membrana tympani are in a state of chronic inflammation and a perforation in the right lower quadrant of the left one. Decided impairment of hearing, especially on the left side. Tongue very pallid, flabby, and coated. A number of small white scars over the anterior and lateral surfaces of the neck indicate the location of the glandular affection from which she suffered during childhood. No general glandular hyperplasia or any other indications of acquired or hereditary syphilis.

Physical examination of the chest revealed nothing abnormal except a point of exquisite tenderness over the junction of the gladiolus and ensiform cartilage of the sternum. Abdomen very much enlarged, the prominence being more pronounced on the left than on the right side of the linea alba. The marked separation or diastasis of the recti abdominis muscles adds greatly to the facility of the examination of the intraabdominal swelling by palpation. By percussion and palpation it was easy to outline the enormously enlarged spleen, which nearly reached the pubes below and extended two inches beyond the median line on a level with the umbilicus. The margin of the palpable part of the spleen is rounded and deeply notched in two places two and a half inches apart in the umbilical region. The splenic dulness extends in an upward direction as far as the sixth rib. The spleen is tender on deep pressure and the patient complains of a sense of weight and discomfort, undoubtedly due to the enormous increase in the size and weight of the organ. Liver enlarged, palpable below the costal arch. Urine, daily quantity, 1,200 c.c. Specific gravity 1.015, amber colored and slightly cloudy, trace of albumin. Microscopic examination shows numerous leucocytes, few epithelial cells, but no casts.

Patient has a slight cough, but examination of the viscid sputum for tubercle bacilli has proved negative. The temperature varies from normal to 100° F.; the slight rise in the temperature was especially noticeable toward evening. Pulse rate from 90 to

110. The slightest exertion caused shortness of breath and rapid pulse. Appetite variable, at times ravenous then followed by loathing for all kinds of food. Carbonate of iron, in the form of Blaud's pills, and Fowler's solution of arsenic were prescribed, and this treatment was continued faithfully for three weeks without making any noticeable impression on the progress of the disease. For the distressing headache the bromides and different coal-tar preparations were administered but gave no relief. The case appeared hopeless when, as a last resort, the *x*-ray treatment was commenced about three weeks after her admission to the hospital. The spleen, the lower end of the sternum, and the epiphyseal extremities of the long bones were exposed to the action of the rays daily for from ten to twenty minutes. When this treatment was begun February 3 the blood examination yielded the following result: erythrocytes, 3,500,000. Leucocytes, myelocytes and eosinophiles, 64,800. Hæmoglobin, 56 per cent. The eosinophiles were numerous and the poikilocytosis was very pronounced. During the course of the treatment the use of the *x*-ray had to be suspended for a day or two on several occasions owing to high temperature and other symptoms of intoxication. The constitutional symptoms became very prominent at the time the spleen first presented indications of progressive decrease in its size, about three weeks after the beginning of the treatment. The blood examinations were repeated at intervals of a few days and it was noticed that improvement kept pace with the reduction in the volume of the spleen. The first decided changes observed were the gradual disappearance of the myelocytes and eosinophiles, and the return of the erythrocytes to their normal shape. An examination of the blood made April 12 showed no myelocytes and only a very few eosinophiles and very little poikilocytosis. March 12 the patient left the hospital, but was treated daily in the outdoor department. The photograph was taken during the second week in June. It gives a correct idea of the area of liver dulness and the size of the spleen before and after the *x*-ray treatment. The patient returned to her home a few days later in excellent health. Menstruation, suspended for a year, had recently returned at regular intervals, and the last blood examination revealed no abnormalities in the structure and relative number of red corpuscles and leucocytes. The patient remained somewhat anæmic, and for that reason was advised to continue the use of a simple iron preparation for an additional number of weeks. I have seen many cases of the different varieties of leukæmia, but this is the only one that has recovered, and this exceptional result I attribute entirely to the prolonged use of the *x*-ray. We have been less fortunate with this new therapeutic resource in the treatment of malignant diseases. I have so far not seen a single case of either carcinoma or sarcoma benefited by this treatment. There can be no longer any doubt in reference to the microbic origin of leukæmia nor of the antimicrobic action of the Röntgen ray. The transillumination of the affected bones undoubtedly accomplished its share in destroying the microbes of the general infective process, as the pain and tenderness disappeared entirely, as well as the occipital headache, during the early part of the treatment. It appears to me that the microbes of splenomedullary leukæmia are very susceptible to the destructive action of the *x*-ray, as the response to this treatment is very prompt and often violent, followed by a speedy return to normal of the spleen, medullary tissue, and the histologic constituents of the blood. The curative power of the *x*-ray in pseudoleukæmia and genuine leukæmia promises to accomplish what heretofore has not been obtained by any kind of medication, and seems to prove that etiologically at least both affections are analogous or at any rate closely allied.



Splenomedullary Leukæmia. Outline of the spleen before and after treatment with the *x*-rays.

## THE MANAGEMENT OF CASES OF PULMONARY TUBERCULOSIS IN THE DISPENSARY.

By JAMES ALEXANDER MILLER, A.M., M.D.,
CLINICAL ASSISTANT IN THE VANDERBILT CLINIC, NEW YORK.

The problem which here confronts us is a very familiar one to all who have had any experience in medical dispensary work. It is a very general opinion that these cases of pulmonary tuberculosis are the most discouraging and the most hopeless, as well as the most common, with which the dispensary physician has to deal.

That interest in them should, therefore, be comparatively slight is very natural, and we need not be surprised to find it confined largely to sympathy for their misfortune and curiosity as to their physical signs.

The first thought is to send these patients to the country, and when this is found to be impracticable, their treatment settles into a perfunctory routine, and the patient subsides into the dreary dispensary habit, encouraged only by the hopes arising from a strange optimism.

We are hearing a great deal nowadays of the "Combat with Tuberculosis," and there certainly is a scientific and philanthropic interest in this disease, more widespread than at any previous time. Its terrifying prevalence is at least becoming recognized, and the hope of an absolute recovery from it in favorable cases has been better established. Our knowledge of the conditions under which it thrives, and, on the other hand, of the requirements necessary for its prevention and cure, has been widely extended. Results of such increased knowledge must surely follow, and we see them already in more efficient sanitary legislation, in tenement-house reform, in lectures and circulars for the education of the people, in a constantly increasing number of sanatoria and hospitals for these patients, and in

organizations especially designed to investigate and prevent the spread of this disease.

All of this work should be heartily supported and extended as far as possible, and no one can fail to appreciate the enormous importance of sustained efforts in these directions.

In the struggle against tuberculosis there is, however, one weak point in the plan of attack, as it has been thus far developed. This, it appears to me, is the unfortunate state of affairs existing in the dispensaries, in regard to these patients. That the dispensary treatment of these cases in New York City is almost universally unsatisfactory, both to the patients and to the physicians, will, I think, be very generally conceded without further discussion. With two or three exceptions, there is no especial care or attention given to these patients in any dispensary of the city. At the Post-Graduate Hospital an excellent work is being done, the published reports of which give very satisfactory grounds for congratulation on the part of those directly interested in it, and for encouragement to those who may hope for equally good results along similar lines in other institutions. It appears to us, however, that even this most excellent work can be very materially widened in its scope when it is applied to dispensaries in general. We believe that the responsibility of the proper dispensary management of pulmonary tuberculosis should not cease with the marked improvement in health of a selected number of such patients, but should include every patient who applies for treatment, and should extend also to a strict regulation and supervision of the home surroundings and personal habits of all these patients. In this way the spread of this disease may be more effectually checked, and the patient, with all his family, enter into cordial and intelligent coöperation with the efforts which are exerted in his behalf.

Since the beginning of the current year an attempt has been made upon a gradually increasing scale to carry out these ideas at the Vanderbilt Clinic. It is the object of this communication to describe these efforts in some detail, and to give a preliminary report of the results thus far obtained.

At the very outset it must be understood that we are here dealing solely with those patients who, for one reason or another, are unable to avail themselves of what is generally acknowledged to be the ideal treatment of their disease. We now know this to be an open-air life, in a favorable climate, with freedom from actual physical or mental exertion, an abundance of the most nourishing food, and under the careful supervision of an experienced medical adviser. All of these conditions we find only in a well-conducted sanatorium. Such sanatoria, however, are unfortunately so inadequate in number and in size, and are regulated by such stringent requirements for admission, that we actually find the whole great mass of the tuberculous poor, for whom there is no provision, relying upon the dispensaries for whatever medical attention they may receive.

When this fact is taken into proper consideration, the great importance of making this dispensary treatment as effectual and careful as possible, is apparent to all who are interested in the eventual solution of this great tuberculosis problem. That such is not the condition of affairs at present may be gathered from what has already been said, and from the general experience of all physicians active in dispensary work.

It is the aim and purpose of the present movement instituted at the Vanderbilt Clinic, to at least make a beginning in the right direction, and gradually to develop a careful and intelligent system of management of these cases of tuberculosis, until such time when public and private philanthropy shall have provided sufficient sanatoria to accommodate all such patients, and thus relieve us of our responsibility toward them. In spite of the very considerable activity now being directed toward that end, we can not but realize that the prospect of any such happy state of affairs is still very remote. We offer our plan as a practical suggestion to dispensary physicians, in the firm conviction that it is possible so to improve upon our ordinary methods of management in such cases, that marked results will be shown in the condition of the patients, in the diminished dangers of transmission of the disease, and in the increasing interest afforded to the attending physician. Moreover, we hope to demonstrate that these results may be obtained with very little increased expense on the part of the dispensary, and that, therefore, no available funds will be diverted from the cause of new sanatoria.

We will consider our subject under two main divisions: (1) The treatment of the patient. (2) The inspection and regulation of the homes.

*The Treatment of the Patient.*—After it is decided in each individual case that proper sanatorium or hospital treatment is not practicable, we accept the responsibility of its management, and our general plan is, as far as possible, to adapt sanatorium methods to the conditions existing at home.

A thorough mutual understanding between physician and patient is essential at the very outset, for in no other way can the necessary coöperation be secured.

The patient should be informed of the nature of his disease, and every legitimate encouragement for ultimate recovery should be given him, but never should he be allowed to forget the seriousness of the situation. A false sense of security is very dangerous, but very common among these patients, and especially is this true of the early cases in young people, whose symptoms are so slight that they find it very hard to realize the underlying dangerous possibilities.

Discouragement, even to extreme mental depression, is also very frequent, and the appreciation and proper management of the state of mind in each patient is very essential to their successful treatment. The danger of infection must be carefully explained, but emphasis should be placed upon the fact that all such dangers may be avoided by the proper care of the expectoration. In the Vanderbilt Clinic each patient is supplied with suitable pocket cuspidors, which have been especially devised for our purpose, and they are also given printed circulars of information concerning their disease, and the general principles of its treatment. The important points are explained carefully to each patient, and upon the results of this first talk will, very often, depend what sort of a patient he is to make, and, therefore, the importance of devoting time and thoughtful attention to it cannot be too strongly emphasized.

The actual treatment rests upon four underlying principles: (1) Rest, (2) Fresh air, (3) Food, (4) Drugs.

The application of these principles to the treatment of tuberculosis in general, is too well known to require repetition, but the modifications of them which are necessary in our dispensary dilemma, will here be considered.

*Rest.*—Among the people of this class, freedom from physical exertion is unknown and generally is impossible. They must live, and in order to live they must work. This is a proposition which admits of very little argument. Rest, however, is a com-

parative term, and there is seldom a case in which a great deal more of it may not be introduced into the daily routine than has heretofore been customary. If the disease is in an active stage, it is of the greatest advantage to give the patient at least two weeks of absolute rest, and if there is fever, this rest should be strictly in bed. In other cases, an easy or reclining chair on the fire-escape or roof is a very satisfactory method of obtaining rest in the open air.

The effect of even so short a time as two weeks spent in this way is often remarkable, and is shown by the subsidence of the fever and by the general improvement of the patient; moreover, there are comparatively few patients who are not able and willing to give up this time for that purpose. When the time comes that they must resume work, they are instructed to avoid all unnecessary exertion or exercise, to rest at odd moments whenever possible, and to rest absolutely after working hours. Whenever the character of their work is evidently having an injurious effect, a change of occupation is advised, and, if possible, actual assistance is rendered toward that end. Employment requiring little physical exertion, and preferably in the open air, is the condition desired, and several of our patients have secured positions as watchmen, janitors, ticket choppers, transfer agents, etc., as the result of our advice. All patients are instructed to rest in the open air as much as possible, to avoid exercise which produces fatigue or shortness of breath and to spend from eight to ten hours of each twenty-four in bed. When a determined effort is made, it is often possible to effect a very fair "rest cure," even while a patient is engaged in active occupation, and, perhaps, supporting a family.

*Fresh Air.*—Methods of obtaining fresh air in connection with rest have already been mentioned. In addition, the patient should sleep in the lightest and best ventilated room of the home, and, when practicable, he should be its sole occupant. In any case a separate bed is absolutely essential. This bed should be so placed that draughts will be avoided, and the window should be kept open continually, provided that the bed covering is sufficient to keep the patient warm. By means of an inexpensive steamer chair and suitable wraps, the patient may rest out of doors, on the roof or fire-escapes, very comfortably, and should sleep there during the summer months. The nearest park should be utilized in favorable weather, as opportunity offers, and all crowded places of amusement or wherever bad ventilation might be expected should be avoided. There is a growing sentiment that the value of any particular climate in the treatment of pulmonary tuberculosis has been greatly exaggerated. While we are not yet disposed to think of New York City as an ideal health resort, nevertheless, the open air even here is certainly beneficial, and we should endeavor to make every possible use of it for these cases. In this connection there is need to protest against indiscriminately sending consumptives to the country, for many localities previously free from this disease have become infected by such patients, who have been ignorant or untrained in the necessary sanitary precautions. No patient should be sent away, unless placed under the direct supervision of a competent physician, until he has demonstrated his willingness and ability to properly respect the health of others.

*Food.*—This aspect of the question is very important but often very troublesome in our work. Gastric disturbances are such a marked feature of this disease, that even under the best of conditions, proper digestion and assimilation are often difficult to obtain. When to this difficulty is added the inability to pay for proper food, and the wretched cooking of that which is procured, the condition of affairs, as regards many of our patients, is accurately described. Our first object should be to correct any digestive disturbance. Rest is again a valuable aid here, and by careful and judicious regulation of the diet, good results may generally be obtained. Much harm is often done by overfeeding before the digestive system is properly prepared for it, and we should carefully and gradually feel our way, until the desired condition of a good appetite and a perfect digestion of a large abundance of food is obtained.

For purposes of superalimentation, milk and raw eggs are the best articles of diet. We gradually accustom our patients to the ingestion of two or three quarts of milk and from six to ten raw eggs every day, in addition to a regular diet of simple food.

The increased expense which this involves is considerable, but many of our patients are able to meet it. How best to supply those patients who are unable to do so for themselves, is a question that has occupied a great deal of thought and attention. We have attempted arrangements with the Diet Kitchen and with grocers, by which fresh milk and eggs should be delivered to our patients at reduced rates, but the practical operation of these arrangements has not been satisfactory.

It is our habit at present to report all these cases to the Committee of the Charity Organization Society for the Prevention of Tuberculosis, and up to this time they have been able to supply all such patients according to the necessity existing in each instance. Our experience leads us to believe that this plan will be found more satisfactory than for the dispensary to attempt an independent means of supply for its own patients, and it has the compensating advantage to the Charity Organization Society in the knowledge that their money is being expended under strict medical supervision.

*Drugs.*—Under this heading would be included the greater part of the treatment ordinarily given to tuberculous patients in the dispensary. Under our plan of management, on the contrary, it is considered of the least importance of all, and the majority of our patients receive no medication whatsoever. Cod-liver oil, to be sure, is largely used during the winter months, but is to be regarded more as a valuable form of food than as a drug. Cathartics must be freely prescribed, as constipation is disastrous during the process of overfeeding, but with this exception, the exhibition of drugs should be carefully restricted, and they should only be used to meet specific indications, such as pain, excessive cough, nausea, anæmia, etc. The stomach is rarely in a condition to bear excessive medication, and the promiscuous use of creosote and similar preparations is to be condemned. In general, less harm is done by too little medication than by too much, and if we err at all, it is preferable to do so upon the safer side.

*Inspection and Regulation of the Homes.*—We consider that this portion of our work is quite equal in importance to the care of the patients themselves. Even should there be no apparent improvement in the condition of the patients, we should still maintain that our efforts would be well repaid by the great benefit to the community derived from this work in their homes alone.

The services of a regularly trained nurse are our mainstay for this purpose. Each new case is referred to her, with any especial instructions or information that may be thought advisable, and after

a thorough inspection of the home, a report is made out by her upon printed forms provided for the purpose and submitted to the physician in charge of the case, together with any suggestions which may occur to her as the result of her visit.

Our general plan is to arrange the whole domestic economy to the best interests of the patient and to provide against the dangers of infection to his household and associates. Careful and detailed instructions are given as to ventilation and the principles of the fresh-air treatment, and practical demonstration is made of the proper method of disinfection of the bed clothing, eating utensils, and personal linen of the patient; also any necessary suggestions are made along the lines of general cleanliness and better hygiene. Thorough inquiry is made concerning the care which the patient habitually takes of his expectoration, and notice taken of the general attitude of the whole household toward the instructions given at the clinic. Carelessness is reprimanded, misunderstandings corrected, and a cordial spirit of coöperation is requested and almost invariably obtained. The daily habits of the patient, the duration and character of his work, his rest, his exercises and his sleep, with the effects of each upon his condition, are ascertained and noted. General destitution, as well as any especial need, is reported, and the attention of a suitable charitable society or institution is directed to it. Particular information is obtained in regard to the patient's diet, his appetite and the nature and cooking of his food. Many digestive disturbances which had taxed the ingenuity and efforts of the physician, are often corrected by a few practical suggestions from the nurse. Investigation is made into the available facilities for taking a "rest cure" out of doors, and the fire-escape, the roof, and the nearest park are all considered from this point of view, and the results incorporated in the report. Sometimes the "home" appears entirely unsuited for our purpose. This may be due to lack of sufficient light or air, to dampness or filth, or because of the distance from the place of work. Under these circumstances, a change is advised and frequently effected, even if aid from the Charity Organization Society or elsewhere is necessary for the purpose. Other members of the household who have coughs, or otherwise excite suspicion, are sent to the clinic for examination, and thus many cases come under our treatment much earlier than would otherwise have been the case.

The nurse is also of great assistance to the physician in her endeavors to explain to these patients and their associates just how great and in what particulars lies the danger of infection to others. The facts must be stated strongly enough really to frighten them from carelessness in regard to their expectoration, but it must be just as strongly emphasized that the freedom from danger is absolute when proper care is uniformly exercised. It would be a most unfortunate consequence of our efforts should our patients be shunned as outcasts by their associates, and both from this misfortune, and from the dangers of infection, we hope to save them and their friends, through their accurate knowledge of the subject. By frequent inspections a general supervision is maintained and assurance is given that the instructions given by the physician are carefully followed. How necessary this is among the class of people with which we are dealing, is a matter of common knowledge.

This cursory review of the part performed by the nurse in our general scheme, needs little discussion to demonstrate its value. It is certainly true, that a woman, trained in nursing, who has the energy, interest and ability necessary for this kind of work can do much more than any physician toward ascertaining the exact condition of affairs and correcting the evils existing in these homes. In no other way could this work be at all complete or satisfactory to the physician, to the patient or to the community, and that these patients themselves appreciate this fact, is evidenced by the warm reception given to our nurse, as a friend and welcome visitor in their homes. We, therefore, consider that she is an indispensable factor in the correct solution of this problem, and as a result of her efforts we can at least say, that each case thus visited is converted from a dangerous focus of infection into a source of accurate and intelligent knowledge in regard to this disease.

Although, as has been elsewhere said, the success of this work is by no means to be measured safely by the percentage of cases which improve or are actually cured, nevertheless it may be of interest to know something of the results thus far obtained as shown by the condition of the patients themselves.

During the months of January, February, and March the plan of management of cases of pulmonary tuberculosis which has been above described was systematically carried out in one of the medical rooms of the Vanderbilt Clinic, representing one-eighth of the total number of patients who applied for treatment in the department of General Medicine. In this room during these three months there were forty-six cases of pulmonary tuberculosis. Eleven of the patients were seen at the clinic only once, and are, therefore, not included in this report. There remain thirty-five cases in which we have had an opportunity to judge of any results of treatment, and these may be classified according to the stage of their disease into: early cases, eight; moderately advanced cases, six; advanced cases, twenty-one.

Of the total number, twenty-two patients have increased in weight, ten have lost weight, and three have shown no change. The average increase per patient in those who have gained weight, is four pounds. The average loss per patient in those losing weight is two and three-quarter pounds. The greatest gain in any one patient is twelve pounds, and the greatest loss is five pounds.

Of the twenty-two patients who gained in weight, seven were early cases, five were moderately advanced, and ten were advanced cases.

Of the ten who lost weight, all were advanced cases and the three cases in which the weight remained stationary represented equally the three stages of the disease. Expressed in percentages, we find improvement in 63 per cent. of all our cases, in 87 per cent. of the early cases, in 83 per cent. of the moderately advanced cases, and in 47 per cent of the advanced cases. In regard to the use of the body weight as an indication of the progress of this disease, it can only be said that this factor is generally regarded to be the best single criterion, and that, while many other conditions must, of course, be considered, the limits of this report render their exclusion necessary at this time. It may be stated, however, that as far as we are able to judge from the clinical manifestations, the changes in body weight furnish a very honest expression of the general condition of these patients.

This incomplete report does not attempt to be in any degree conclusive, because of the small number of cases and of the short time that they have been under observation. Nevertheless, it must be admitted that these results afford encouragement to us in the further prosecution of this work, and they are only presented here in order

to demonstrate that our plans are not entirely idealistic or impracticable, and to stimulate, if possible, a greater interest in these cases upon the part of others.

The object of this communication has been accomplished if it directs attention from the physicians active in dispensary work to the problems which are here considered. Although the work in itself is comparatively inconsiderable, we feel that it is a good beginning in a somewhat neglected field, and if all the dispensaries in the city should be aroused to a similar interest and activity, we would immediately have a tremendous force applied to the solution of the tuberculous problem and one that is not dependent upon large public subscriptions for its execution.

The writer wishes to express his sense of deep obligation to Dr. Edward L. Trudeau, to whom is due his especial interest in this whole subject, and to Prof. Walter B. James, without whose invaluable coöperation and generous support this particular work would have been impossible.

550 Park Avenue.

## SECRET POISONS AND THEIR USES IN ANCIENT TIMES.

By J. W. WAINWRIGHT, M.D.,
NEW YORK.

Reference as to what is known of the poisons used in secret by the ancients, as well as those of the sixteenth and seventeenth centuries, including some historical illustrations, it is thought will prove of interest, not only to those having to do with medicines, such as physicians and pharmacists, but to those interested in ancient and medieval history as well.

Because of a fear of extending the practice of using secret poisons to rid one of an enemy, an objectionable husband, creditor, or such persons as were thought to interfere with the advancement of one's person or interests, governments, when they came to a knowledge of the substances used, endeavored by all means to suppress the information, and this accounts in a large measure for the meager information obtainable. Poisons were used, however, as history tells us, very freely; even as early as in the times of the ancient Greeks and Romans. That they were then so successfully and skilfully used, would indicate that their action has been understood for many years previous to their times.

Poisons were known to and used by the ancient citizens of Greece and Rome, and it is claimed in such a manner as to occasion death at a previously determined time. In the light of our present knowledge of the action of poisons, it is not understood how this could have been literally true; or, if it was measurably so, the knowledge of the professional poisoner of those times and the substances used is lost to us of to-day, for we know that so many factors enter into the action of poisons, idiosyncrasies, resistance, susceptibility, and other features, that with all of the knowledge of to-day the most experienced practitioner of medicine cannot always determine just what the effect will be when remedies classed as poisons are administered for therapeutic purposes. We have numerous instances of whole families or companies partaking of the same food with disastrous results to some, only temporary effect on others, while there were those who escaped injury. To mention a classic case in illustration: Pope Alexander VI died in 1503 from partaking of poison at a banquet, while Cæsar Borgia, his son, recovered without loss of health, although he had drank through mistake of the bottle containing the poison intended for the guests.

Plutarch, Quintilian, and others of the earlier writers described the effects of these poisons, Plutarch in particular stating that "a slow poison, which occasioned heat, a cough, spitting of blood, consumption, and a weakness of intellect was administered to Aratus of Sicyon." This poison was not speedy or violent in its action, Aratus lingering for some time; on an occasion when he spit blood, he remarked, "This is the effect of royal friendship." Quintilian in his declamations speaks of this poison in a way to impress one that it was well known. A knowledge of chemistry was not necessary to prepare these poisons, as we know that all savages and particularly the American aborigines were acquainted with such substances, and often employed them with such skill that it was impossible to guard against treachery, the victim invariably dying after a lingering illness, sometimes at the expiration of months or years.

Theophrastus, who lived some two hundred and fifty to three hundred years B. C., and who was a pupil of Plato and afterward of Aristotle, in his "History of Plants," one of the earliest works extant on botany, writes of "a poison which could in its use be so moderated as to affect the victim in two or three months, or even at the end of one or two years," and states that "the death, the more lingering it was, the more miserable." This poison, according to this Greek philosopher, was prepared from aconite, which, because of its death-dealing properties, was forbidden to be handled by the people, or to be found in their possession under the penalty of capital punishment. He also states that other plants were in use in the preparation of poisons, and cites a discovery of Thrasyas of a method of preparing a poison which when given in drachm doses, occasioned an easy but certain death, without pain, and whose action could be controlled for long periods without causing suspicion. This was the poison so much used in Rome about two hundred years before the Christian era. A number of persons of distinction died within a short period of time with like symptoms of poisoning, and an inquiry was instituted, which resulted in the conviction and punishment of more than one hundred and fifty ladies of the first families, the evidence being procured through a maid servant.[1] But so many had learned the art, that it was found impossible to suppress it, as the knowledge was continually possessed by those willing to risk its practice.

Sejanus caused a secret poison to be administered to Drusus Cæsar, a quæster of the people of Rome, A. D. 22, by a eunuch at the command of Livia, the wife of Sejanus and mistress of Drusus. Drusus gradually declined as by a consumptive disorder, and finally died. Agrippina, the mother of Nero, being desirous of disposing of Claudius for political reasons, caused a poison to be prepared by an expert poisoner, Locusta, who had been already condemned to death for her infamous practices, but saved that her nefarious art might be employed. The poison was given the emperor in a dish of mushrooms. This same Locusta prepared the poison with which Nero dispatched Britannicus, the son of Agrippina and his half-brother, whom his father, Claudius, desired to succeed him as emperor. This poison, we are told, caused the death of Britannicus as soon as taken.[2] For this service the emperor pardoned Locusta, rewarded her liberally, and gave her pupils to instruct in her art in order that it might not be lost.

"This poison, whatever it may have been," says John Beckmann in his "History of Inventions and

Discoveries," London, Vol. I, p. 50, from which history I have largely drawn in preparing this essay, "was known in Carthage, for Tuditanus, whose work is now lost, but who is quoted by Aulus Gellius, Lib. VI, c. 4, declares that Marcus Attilius Regulus, a famous Roman general, who, after numerous victories over the Carthaginians, was finally taken prisoner by them, and later sent to Rome to effect an exchange of himself for some Carthaginian prisoners. His captors had, however, taken the precaution to administer to him a poison which would soon, after the exchange was made, render him useless to his countrymen, by death. Knowing this before leaving Carthage, and that he would be of no further use to Rome, he advised strenuously against the exchange, appearing in the Senate for that purpose. Refusing a parole, he returned to Carthage, when in revenge for his advising against the exchange, he was cruelly tortured to death, the action of the poison not being sufficiently energetic to save him from the torture, besides such a death was regarded by his enemies as too mild a punishment.

We are reasonably certain that these poisons were made from plants, such as aconite, hemlock, and poppy, particularly the latter, although Philostratus[3] declares that some were made from animal substances, mention being especially made of one prepared from the sea-hare (aplysia), a mollusk remarkable for the function of secreting a fluid of violet color, due to the presence of iodin, which they discharge when molested. Its administration is said to have caused speedy and inevitable death to man. What part of the mollusk was used, or that it was the violet-colored fluid, does not appear.

This was the poison, according to Philostratus, which was used by Domitian to dispatch Titus. Dioscorides, Galen, Nicander, Aëtius, Aelian,[4] Pliny,[5] and others mention it in their writings.

Its use, however, produced peculiar symptoms, which were readily recognized, thus leading to detection.

We do not think that it was, therefore, very extensively used.

That the ancients made use of a form of arsenic known as orpiment (arsenic trisulphide) is reasonably certain, but it was not until the seventeenth and eighteenth centuries that the powerfully destructive corrosive metallic arsenous oxid or acid became the principal ingredient in the secret poisons which were used with such diabolical perfection in France and Italy.

In the seventeenth century, secret poisoning developed into an epidemic, spreading rapidly over western Europe. It became a regular branch of education, and was practised by those who professed a knowledge of chemistry, magic or astrology. The practice became very lucrative not only in the sale of the poisons, but of the secret of their composition as well. The art was practised in England to a considerable extent as well as in France and Italy. In King Henry VIII's reign, an act was passed by Parliament declaring the employment of secret poisons to be high treason and inflicting a penalty of being boiled to death for those found guilty of making use of the same.

Sir Thomas Overbury was poisoned by Viscount Rochester in the reign of King James VI. Some writers assert that King James I was a victim of secret poisoning by the Duke of Buckingham. In fact, we are told that a "Doctor Lamb," a conjurer and quack, was believed to have furnished the poison to the duke for the purpose, and that he was, therefore, beaten and stoned to death by the angry populace in Cheapside.

In Italy, the use of secret poisons was regarded as a justifiable procedure to rid one of a rival or enemy. Italian history informs us that poisoning was the favorite weapon of the oppressed and the oppressor, not only for protection but for revenge. The notorious family of Borgias is referred to more frequently than others, but they were by no means alone in this practice. Cæsar Borgia and his sister Lucrezia were children of Rodrigo Borgia, afterward Pope Alexander VI, by a Roman woman, Vanozza by name. Alexander VI died from partaking of poison, as elsewhere stated, at a banquet which he and his son Cæsar an active military adventurer and cruel despot, had prepared for twelve cardinals. Father and son had long been familiar with this mode of dispatching those who stood in the way of their ambition, or whose wealth they desired to obtain. Cæsar Borgia had received from his father, the Pope, high ecclesiastical preferment, in fact, being invested with the purple. He became envious of his brother Giovanni's good fortune and caused his assassination, resigned from the Church, and gave himself up to his ambitious designs. Lucrezia, the sister, was popularly believed to have been the most active in ridding herself of her enemies, through the means of secret poison, but recent investigations have demonstrated that she was a too pliant instrument in the hands of her father and brother. She died June 24, 1519, enjoying the respect of her subjects. Assassination was, in these times, regarded as an unpardonable crime, but poisoning, if not justifiable, at least excusable.

The Roman Church was made acquainted, through the confessional during the papacy of Alexander VII (1659), with the frequency of the crime in Rome. Young widows were extremely numerous and unhappy marriages were rapidly put an end to through sickness followed by death of the husband. Inquiry resulted in the discovery of a secret society, of young wives which met at the home of one Hieronyma Spara, an old hag who was regarded as a witch, and who ostensibly earned a living by telling fortunes. The whole society were arrested through a woman of distinction presenting herself and representing a desire for some of the drops with which she wished to rid herself of a cruel and tyrannical husband. All were put to the torture. As a measure of warning to those who practised secret poisoning, Spara, her assistant, Gratiosa, and thirteen other women were publicly hanged. Later other members of the society were whipped naked through the streets, whilst some were banished from Rome. Notwithstanding these heroic measures, the crime of secret poisoning prevailed.

Some fifty years after Spara's (sometimes written La Spara) exposure a similar organization was discovered in Naples, presided over by an old woman named Toffania, formerly of Palermo, and by many believed to be a pupil of Spara, who manufactured a poison similar to that used by Spara. This was sold extensively in Naples, as well as charitably given to those who wished to rid themselves of their husbands, under the name of aqua Toffania, or aqua della Toffania, aquitta di Napoli and aquitta. From four to six drops were sufficient to destroy a man (doses are never given for women, for the reason, perhaps, that they were not required to take the stuff, the men being the only sufferers), and the claim was made that the dose could be so regulated that it would operate only and surely at a certain fixed time. This leads me to remark that with the exceptions of Pope Alexander VI and his son Cæsar Borgia, the poisoners of history have been women. This poison was sent to all parts of Italy as Manna of St. Nicholas

of Bari, this being the name also of an oil renowned for its miraculous cures of many diseases, which was procured from the dropping from the tomb of St. Nicholas at Bari, a popular saint of the Church, whose feast is still honored, especially in Russia and Germany, the patron saint of children, and the same as Santa Claus or St. Nicholas of our Christmas time. The supposed relics of St. Nicholas were conveyed from the East to Bari in the Kingdom of Naples toward the close of the eleventh century.

The reputed sanctity of this oil (?) and its large use prevented the authorities from a close examination of the poison. Toffania—or as sometimes spelled Tophania—was at length suspected (1709), when she fled from one to another convent, where she claimed and received immunity from arrest because of the ecclesiastical protection given those who sought the sanctity of these places. She was finally seized, however, and thrown into prison. Being put to the rack, she confessed to having herself caused the death of more than six hundred persons, and named those who patronized her. She was finally strangled to death in 1719. Those whom she named in her confession as patrons were apprehended, some at their devotions in churches, some in monasteries or convents and others in their homes. This did not, however, put a stop to secret poisoning, for Keysler says that it was still in vogue in Naples in 1730. The art of poisoning was brought to light in France in 1670,[8] the agents being, as in Rome, Italy, and elsewhere, married women, and the victims their unfortunate husbands and lovers. This knowledge was made known to the authorities, also, as in Rome, through the confessional. Margaret, wife of the Marquis de Brinvillier, through her paramour, Godin de Sainte Croix, became possessed of the secrets of preparing poisons, Sainte Croix securing his information from a fellow-prisoner while in the Bastile at the instigation of Margaret's father. She assumed the apparel of a nun, visited the sick in the Hôtel-Dieu and gave them her poisons in lieu of medicines for the purpose of testing their strength. She also caused poison to be given her father, brother, and sister, hoping by their deaths to better her own and Sainte Croix's circumstances through acquiring their property. The father and brother succumbed, but the sister, who had become suspicious, did not take the poison intended for her.

This Sainte Croix, while preparing his poisons, was accustomed to wear a glass mask. Through an accident one day while at work in his laboratory this mask dropped off, when he was suffocated to death. Being without family, the Government took possession of his effects, and upon examining the articles in the laboratory, discovered a box containing a number of bottles of poisons with labels on each, telling of their effects on animals. This box was directed to the Marchioness de Brinvillier and written instructions left to either deliver to her or destroy the contents. Upon this becoming known to the Marchioness, she fled, as usual in such cases, to a convent. She was, however, in time enticed from this privileged place by a detective, disguised as an abbé, and thrown into prison, where she confessed, was tried, convicted, beheaded, and afterward her body burned.

Secret poisoning continued in France notwithstanding this example, many persons dying under suspicious circumstances. Again the clergy gave warning to the authorities that many persons of high as well as of humble rank confessed the crime, and a court of inquiry was instituted in 1679, known as the *Chambre Ardente*. This court exposed two women who were carrying on a great traffic in poisons, named La Vigoreux and La Voisin, the latter a midwife. Both were fortune-tellers as well as vendors of poisons to those desirous of being rid of cruel husbands or recreant lovers. Ladies of the first rank, and even some belonging to the court, patronized these wretches. In the possession of La Voisin was found a list of such women as had consulted her and purchased poison. La Vigoreux and La Voisin were burnt alive on the 22d of February, 1680, after their hands had been bored through with red hot irons and cut off. Several of the patrons of ordinary rank were publicly hanged. Those of higher rank were set at liberty.

The crime of secret poisoning has been practised in other countries than those mentioned. Count Corfitz de Ulfeld of Denmark was suspected of giving the king poison, while Charles XI, King of Sweden, died from the effects of poison April 15, 1697. During his illness he asked his physician what was the cause of his distress, and was told that: "Your majesty has been loaded with too many maledictions."

Aside from the reference made to King James I and Sir Thomas Overbury's deaths from poison in the earlier parts of this essay, we have no positive historical knowledge of the practice in England. It is true that Shakespeare refers to secret poisoning in several of his plays, notably in "The Tempest," Act III, Sc. 3, when Gonzalo remarks:

> "Like poison given to work a great time after,
> Now 'gins to bite the spirits."

Here we have the idea elsewhere referred to, that poison could be given without those taking it being aware of having done so, and that it would work at some remote and determined period.

Again in King John, Act V, Sc. 7,

> *Hubert:* The king, I fear, is poisoned by a monk:
> I left him almost speechless, and broke out
> T' acquaint you with this evil; that you might
> The better arm you to the sudden time,
> Than if you had at leisure known of this.
> *Bastard:* How did he take it? Who did taste to him?
> *Hubert:* A monk, I tell you; a resolved villain,
> Whose bowels suddenly burst out: (diarrhœa) the king
> Yet speaks, and, peradventure, may recover.
> . . . . . .
> *King John:* There is so hot a summer in my bosom,
> That all my bowels crumble up to dust:
> I am a scribbled form, drawn with a pen
> Upon a parchment; and against this fire
> Do I shrink up.
> *Prince Henry:* How fares your majesty?
> . . . . . .
> *King John:* Poisoned—ill fare—dead, forsook, cast off;
> And none of you will bid the winter come,
> To thrust his icy fingers in my maw;
> Nor let my kingdom's rivers take their course.
> Through my burnt bosom; nor entreat the north
> To make his bleak winds kiss my parched lips,
> And comfort me with cold.

This is, I think, clearly a case of arsenical poisoning.

In Winter's Tale, Act 1, Sc. 2, Camillo says:

> Sir, my lord,
> I could do this; and that with no rash portion
> But with a ling'ring drachm, that should not work
> Maliciously like poison.

And in Cymbeline, Act V, Sc. 5:

> *Cornelius:* She did confess she had
> For you a mortal mineral; which, being took,
> Should by the minute feed on life, and ling'ring
> By inches waste you.

The learned class in Shakespeare's time and for ages before were much given to the study of chemistry, and in a way, pharmacy; chemistry in the hopes, largely, of securing fame and fortune, phar-

macy more for the poisonous substances than the curative remedies. Here is even a queen engaged in the study of poisons under the tutelage of good doctor Cornelius.

Then we have the classic speech of Friar Lawrence in "Romeo and Juliet," Act II, Sc. 3:

*Friar Lawrence:* "Now, ere the sun advance his burning eye,
The day to cheer and night's dank dew to dry,
I must up-fill this osier cage of ours
With baleful weeds, and precious-juiced flowers

Many for many virtues excellent,
None but for some, and yet all different,
O, mickle is the powerful grace that lies
In herbs, plants, stones, and their true qualities:

Within the infant rind of this weak flower
Poison hath residence and med'cine power:
For this, being smelt, with that part cheers each part,
Being tasted, slays all senses with the heart."

The apothecary to Romeo:

*Apothecary* "Put this in any liquid thing you will,
And drink it off; and, if you had the strength
Of twenty men, it would dispatch you straight."
—Romeo and Juliet, Act V, Sc. 1.

In "Hamlet" reference is made to the poisonous effects of hemlock, as well as of poison so powerful that when applied to a scratch in even infinitesimal quantity certain death follows. There is warrant for this statement, as it is well known that South-American natives point their arrows with curare. No authoritative records are obtainable to show the anatomical lesions produced by these poisons, and much of our information is therefore empirical; still, enough is at hand to show that both irritants and narcotic substances were used. That Toffania, that modern Medea, used a solution of neutral salts of arsenic seems to have been established by Hahnemann.[9] Garelli thinks that it was a crystallized arsenic (arsenious acid) dissolved in water. This solution was, at all events, colorless, and "acted by destroying the appetite and the respiratory organs." Pitaval describes the symptoms occurring before and lesions found after death in the case of these slow poisons. "After having languished for a long time, he was seized with a loathing for every kind of food; the vomitings continued until nature being at length exhausted he expired without fever. During the last few days the victim wasted very much, became extremely shrunken and complained of great heat in the stomach. When, after death, the viscera was examined, part of the duodenum was found to be black and sloughed off in pieces (gangrene); the liver was mortified and, as it were, burnt." These symptoms and lesions clearly point to arsenical poisoning, the length of time intervening before death being doubtless due to the small and frequent dose.

Aquafortis (nitromuriatic acid) was thought to form the principal ingredient in some of the poisons and was therefore forbidden in Rome. I, however, regard this highly improbable, as the intensely acid taste of aquafortis would disclose a foreign substance in food or drink. In Paris it was believed that finely powdered diamond dust was the so-called succession powder—so named because of its use in royal households to secure a successor to the reigning king. Baldinger, on the other hand, has no doubt but that the succession powder of the French and Italians owed its poisonous properties to sugar of lead. In the casket of Sainte Croix, referred to elsewhere in this essay, were found corrosive sublimate, opium, regulus of antimony (antimony sulfid), vitriol (zinc sulfate), and a number of poisons ready prepared, the ingredients of which the physicians who examined the contents of the box were ignorant. Toad-flax, a common perennial weed, also called devil's flax, flaxweed, butter and eggs, etc., has been mentioned as a poison used secretly, but I think if it were used at all, it was probably to disguise other and more active ingredients. A mixture of opium and cantharides has been referred to by numerous writers as producing extremely poisonous effects. In proper proportions it is said to form a solution without taste or color. Abbé Gagliani[9] declares "this liquid to be as limpid as rock water; that its effects are slow and imperceptible when given a few drops in tea, chocolate, or soup." It is from this mixture that the dauphin, father of Louis XVI, died on December 20, 1765, and the dauphiness in 1767. Continuing, the Abbé declares that "there is not a lady in Naples who has not some of this poisonous mixture lying carelessly on her toilet table with her smelling bottle. She alone knows the phial. Even the waiting woman, who is her confidant, is not in the secret, and takes this phial for distilled water, which is used to moderate my lady's perfumes when too strong. The effects of this poison are very simple. A general indisposition is at first felt in the whole frame. The physician examining you, and perceiving no symptoms of disease, either external or internal, no obstructions or humors, no inflammations, orders detergents, regimen, and evacuation. The dose of poison is then secretly doubled, and the same indisposition continues without being more characterized. The physician who can see in this nothing extraordinary, ascribes the state of the patient to vicious and peccant humors, which have not been sufficiently carried off by the first evacuation. He orders a second—a third dose—a third evacuation—a fourth dose. He then sees that the disease, whatever it may be, has escaped him; that he has mistaken it, and that the cause cannot be discovered, but by changing the régimen. In a word, the nobler parts lose their tone; become relaxed and affected, the lungs particularly, as the most delicate of all, and one of the most employed in the functions of the animal economy. The first illness then carries you off, because the critical accumulation settles in the weaker part, and consequently on the lobes of the lungs; pus then fixes itself and the disease becomes incurable. By this method they follow one as they choose, for months or for years. Robust constitutions resist for a long time. In fact, it is not the liquor that kills, it is rather the different remedies which alter and then destroy the temperament, exhaust the strength, extenuate and render one incapable of supporting the first indisposition that comes."

The Abbé declares the aqua Toffania a compound of opium and cantharides.

Garelli,[10] who was physician to the emperor Charles VI, king of the two Sicilies at the time of Toffania's career, wrote to Hoffmann in 1718 of "a poison, slow in its action, which was nothing else than a solution of crystallized arsenic in a large quantity of a decoction of cymbalaria." This was the poison used by that infamous Toffania, a fact communicated to the emperor through the judicial procedure of convicting this female, confirmed by a confession. Upward of six hundred persons perished through this woman. It will be seen that there is conflicting testimony as to the active ingredient used by Toffania in the preparation bearing her name, and this can be accounted for through the efforts of the authorites to keep the secret from the public, all information being, as a rule, destroyed with the convicted poisoner.

A poison was used in the East Indies[11] under the name of *powst*, which is said to have been made by steeping the juice of poppies from which opium is obtained over night in water. It was given in the morning while fasting, and particularly to those whom it was desired should perish without violence. It is said to effect the victim slowly, death being ushered in with the classic symptoms of opium poisoning. So, I repeat, absolute knowledge of the particular substance used in secret poisoning in ancient times is not accessible. Formulas when found were usually burned with the criminal. Then the lack of accurate pathological action, symptoms, and anatomical lesions leaves us wholly unable to determine the article. Irritant poisons occasion, when taken in toxic doses, vomiting, purging, and severe abdominal pain. They act chiefly upon the stomach and intestines, causing destruction of tissue, perforation or gangrene. There are, however, articles classed as irritant poisons which do not exert a distinctive chemical action on the tissues with which they come in contact; cantharides and lead salts are notable examples. Narcotics act especially on the brain and spinal cord, the symptoms being vertigo, headache, loss of, or double, vision, stupor, loss of power of the voluntary muscles, convulsions, and finally coma. Special characteristic symptoms often accompany the use of narcotic poisons resembling special diseases. Thus coma from a toxic dose of opium closely resembles apoplexy, while strychnia gives rise to convulsions resembling those of epilepsy.

We have also the narcotico-irritants which have a mixed action. At first they produce vomiting and purging like the irritants. This is soon followed by stupor, coma, paralysis, and convulsions. Familiar examples of this class are aconite, and the ptomains found in decayed meat, fish, and mushrooms. Any one of these classes may be, and doubtless were, used in the early secret poisoning, or, indeed, a mixture such as opium and cantharides so prominently mentioned may have been as largely used as indicated above. That secret poisoning prevailed to a frightful extent is certain. Happily, it is rarely practised now, although a case recently came to light in Massachusetts in which a professional female nurse confessed to having caused the death of sixteen persons whom she was employed to attend, by administering morphine in repeated small doses.

Other cases might be mentioned, but would, I think, be out of place in an essay treating of ancient poisons and poisonings.

**The British Imperial Service Medal for a Nurse.**—According to the London *Hospital*, there has been the name of but one nurse, in the long list of recipients of the Imperial Service medal, namely, Mrs. Margaret O'Regan. Until she was pensioned Mrs. O'Regan served at Kilmainham Hospital, Dublin.

## PURPURA HÆMORRHAGICA FULMINANS, WITH REPORT OF A CASE.

By HENRY GRAHAM MacADAM, M.D.,
NEW YORK.

The term purpura is applied to certain morbid conditions, characterized by multiple hemorrhages into the skin, the cause of which is more or less a matter of speculation. Schacher, in 1723, described two forms of this affection: Purpura maligna, occurring in malignant fevers, and purpura benigna, a mild form without fever. Sauvages, in "Nosologia Methodica," in 1769, describes purpura senilis under the name ecchymoma melasma, and refers back to the time of Galen. Previous to Sauvage's writing, however, Werlhof, a physician to George III in Hanover, presented (1735) a detailed description of purpura hæmorrhagica, and this condition has since that day been recognized very generally under the name morbus maculosus Werlhofii.

*Etiology.*—There are many well-known conditions in which cutaneous hemorrhages occur with or without hemorrhages from mucous membranes and into internal viscera. Among such are the exanthemata, pyæmia, septicæmia, and malignant endocarditis, in which it is supposed the blood vessels are, in part, destroyed by the toxins excreted.

Purpura is also seen in certain cases during the administration of drugs, as potassium iodide, phosphorus, copaiba, quinine, belladonna, mercury, and ergot. Again, we may have it in snake poison, pernicious anæmia, leukæmia, tropical diarrhœa, scurvy, cancer, tuberculosis, Hodgkin's disease, Bright's disease, in association with jaundice and in old age. Lastly, it is seen in the course of certain neurotic affections, such as locomotor ataxia, myelitis, and neuralgia.

In these various conditions the bleeding is known to be a symptom, which is usually, but by no means always, of comparatively minor importance. And it is possible that, in the condition of which we are treating, the purpura is only a symptom of an acute infectious disease. In the type known as purpura hæmorrhagica, however, the hemorrhages constitute the most obvious symptom. But, as will be seen, we are practically ignorant of the pathological conditions giving rise thereto.

Many classifications of purpura have been adopted, and it has been found exceedingly difficult to get at any that is entirely satisfactory; but for purposes of description, and having particularly in view the object of this article, the division made by Osler, apart from its intrinsic merit, will be found most convenient: (*a*) symptomatic, (*b*) arthritic, (*c*) hemorrhagic.

This article is not intended to traverse the field of purpura at large, but is addressed specifically to the type marked C in above category, and to that type we will now, as far as feasible, confine ourselves: Purpura hæmorrhagica, in which hemorrhage is the predominant, if not the only, feature. Many microorganisms have been described as occurring in this form of purpura, and numerous theories as to its etiology advanced.

William Koch believes it to be allied to scorbutus and other hemorrhagic affections. Ajello and Schwab regard it as an acute infection—a form of toxæmia. Kolb, Tizzoni, Babes, and Claisse have found various bacteria in the blood in fatal cases. Lebreton and others have isolated streptococci and staphylococci from the blood of patients having the hemorrhagic purpura. Claim to have isolated a specific bacillus—the bacillus purpuræ—which closely resembles the bacillus of anthrax, was made by Letzerich, as early as 1889. Petrone and others claim that the subcutaneous injection into rabbits

of the blood from patients with hemorrhagic purpura will cause a like affection in these animals.

Strümpel, in the last edition of "A Text Book of Medicine," says "it is not impossible that continued investigation will deprive morbus maculosus of its individuality as a specific form of disease and show that it is merely a special form of profound sepsis."

The term fulminating is applied to cases characterized by great malignancy and suddenness of onset and development, death often occurring within a few hours. This form usually occurs in young and apparently healthy children—more frequently in girls. Occasionally it is seen in adults. It is never epidemic. Jacobi, in "The Therapeutics of Infancy and Childhood," says: "The suspicion appears justified that the fulminating type of purpura is an acute infectious disease." In view of the researches of these keen observers, the uncertainty of their conclusions and the divergence of opinions among them, we must confess that the origin of this disease, or symptom, if you please, is at the present time unknown. We can say only this, that purpura hæmorrhagica fulminans is a rare affection, and generally results fatally.

*Pathology.*—Hemorrhages, from the size of the head of a pin (petechiæ) to that of a silver dollar (ecchymoses), are found in various parts of the body, in all the stages of discoloration which extravasated blood passes through. In the fatal cases smaller or larger extravasations are also found in all the viscera and in the serous and mucous surfaces. There is usually marked anæmia as a result of the severe hemorrhage, and often nephritis is present. Swelling of one or more joints has been recorded, but this is infrequently seen. Endocarditis may be present. In a few rare instances intestinal ulceration with perforation and consequent peritonitis has been observed. There may also be present an acute enlargement of the spleen and liver.

*Symptoms.*—In the fulminating type of hæmorrhagic purpura the invasion is generally rapid and severe, the bleeding taking place not only into the skin, but into the mucous membranes and all the internal organs and tissues. The bleeding from the nose is especially severe and at times uncontrollable. Hemorrhage from the gums and palate has long been recognized as characteristic of the disease. The patient is usually overwhelmed by the hemorrhages, and dies from within a few hours to two days.

Holt says it is almost invariably fatal. In certain cases there is a short prodromal period, characterized by loss of appetite, general malaise, and indefinite pain for one or two days previous to the bleeding. The temperature usually rises even as high as 105°, but often there is no fever at all. Death may ensue merely from the loss of blood or from exhaustion, œdema of the lungs, or apoplexy. A severe hemorrhage may occur into the viscera without any external evidences and death result in a short time. Occasionally the hemorrhages cease, and the patient gradually recovers; convalescence sometimes being prolonged over a number of months.

*Diagnosis.*—There is no recorded condition that can be mistaken for the typical fulminating hæmorrhagic purpura. The sudden and violent invasion, with or without a rapid rise of temperature, bleeding into practically every tissue and organ in the body, with consequent marked anæmia, and the waxy skin, and rapid labored breathing, with or without unconsciousness, combine to make a picture so strikingly characteristic that once seen it is never forgotten. In a few cases, however, the onset is preceded by one or two days of lassitude and loss of appetite, with occasional petechiæ appearing on the skin and mucous surfaces. In these cases it is difficult to make a positive diagnosis until the severe hemorrhages make their appearance. In the mild cases it may be distinguished from leukæmia by the swollen glands seen in the latter, together with what is revealed by an examination of the blood.

Differentiation from scurvy is made by the affection of the gums and history of a faulty diet. It may be difficult in some cases to exclude hæmophilia, but usually the family history and a consideration of all the facts will be sufficient to make the diagnosis clear. The malignant forms of fevers, particularly measles and smallpox are distinguished by the prodroma and the higher temperature.

*Prognosis.*—While in symptomatic and arthritic purpura, the prognosis is favorable, recovery taking place commonly in a few weeks, the general view is that in hæmorrhagic purpura the prognosis should be guarded.

As to the fulminating type of hæmorrhagic purpura, however, a review of authorities leaves much to be desired, a condition arising undoubtedly from the fact that cases of the fulminating type are exceedingly rare. Holt says that in cases of this class, "the prognosis is almost invariably fatal." Osler makes the statement that "these cases may prove fatal within twenty-four hours." Many authors, without explicitly mentioning the fulminating type, join in the view that in purpura hæmorrhagica the prognosis should be guarded, but qualify by observing that while in general there are fair chances of recovery, those cases in which hemorrhage into the internal viscera appears usually have a fatal termination.

It will be seen that this qualification practically puts in a class by themselves the cases which verge upon, or which are actually included in, the type distinguished as purpura fulminans. So that there is practically a consensus of opinion that in cases of the fulminating type the prognosis is fatal. Whether this view may be modified by consideration of the case about to be described is for the reader to determine.

*Treatment.*—The general treatment consists of confinement in bed with absolute rest; care being taken to avoid any exposure. The slightest injury or pressure on any part of the body way be sufficient to cause an increased hemorrhage. In medication, locally and constitutionally, drugs almost innumerable have been employed, prominent among them being: hydrastis, aromatic sulphuric acid, hamamelis, ergot, gallic and tannic acids, arsenic, oil of turpentine, antifebrin, calcium chloride, perchloride and persulphate of iron, and acetate of lead. It is manifest from the well-nigh interminable category that the medical profession has been seeking the constitutional hæmostatic with anxiety, but without determinative result. Osler says: "We are still without a trustworthy medicine which can always be relied upon to control purpura—the whole series of hæmostatics may be tried in succession without any benefit."

CASE. January 10, 1903. Mary D., age five years. Family history good, except phthisis on father's side; one brother dying of consumption. Child's father and mother have always been in perfect health. Four other children, health normal. There has never been a case of hæmophilia or purpura in the family. I was called to see the child on January 10 at 11 A.M. The mother gave the following history: The child has always been unusually well, strong and robust, and full of mischief, never had any ailment, with the exception of an uncomplicated attack of scarlet fever two years ago.

On Friday, January 9, the mother noticed that the child was "drowsy and heavy" in the morning. In the afternoon three black and blue spots made their appearance on the child's forehead. At this time she was very much brighter than she had been in the

morning. The mother inquired if the child had met with an accident, but could get no history, so concluded to call a physician. At 11 A.M., January 10, when I saw the child first, it was bright, rosy-cheeked, playing around the room with the cat. Being stripped, she was seen to be covered with petechiæ, and there were some half dozen ecchymotic spots on the body. The condition was recognized as purpura, and the mother was told of the possibility of its being one of those rare types of purpura, namely, the fulminating, and accordingly advised to take the child to the hospital.

At 11.30 A.M., I was sent for hurriedly, and being unable to attend, another physician was sent in my place. The child was found almost moribund—unconscious, ashy-white, bleeding from the nose, stomach, lungs, bowels, kidneys, etc., head thrown back, mouth opened, breathing rapidly and laboriously; no pulse perceptible. The child had vomited several pints of blood. Local applications of adrenalin chloride 1-1000 were made to the nose only, and the mother was told that it was useless to take the child to the hospital, as she was practically dead. On call of a neighbor, an ambulance came, but the surgeon refused to take the case, stating that the child could live but a short while.

I saw the patient again within an hour, and the child had been vomiting blood since my previous visit. The case looked hopeless. However, chancing an heroic measure, I administered twenty drops of adrenalin solution in a tablespoonful of water internally. At the end of fifteen minutes the child regained consciousness. A little color appeared in the cheeks and the pulse was perceptible at the wrist. I gave ten drops of adrenalin. The child continued to show evidences of improvement. Then I had the child taken to the Post-Graduate Hospital. She remained there from Saturday, January 10, until the following Tuesday. At the hospital she received ten minims of adrenalin every three hours in orange-juice, no nourishment being permitted.

January 10, 1903. On admission to the Post-Graduate Hospital, the rectal temperature was 98.6°, pulse 140, and respiration 28. Examination revealed large purpura spots, three on right arm and two on the left arm, size of a quarter of a dollar; two on back, size of a half dollar, and small spots of various sizes over the entire body. In the left sclera two bluish spots external to cornea one-quarter inch. Stools normal; no hemorrhage from the vagina or rectum.

January 11, urine, specific gravity, 1026; acid. No sediment; albumin present; no sugar; no indican; hyaline casts were present; few pus cells, no blood, bladder epithelium; no crystals; some mucus.

January 12, 12.30 A.M. Hemorrhage occurred from the right nostril, which was packed.

January 13, 2 P.M., slight oozing from right nostril; repacked. Discharged at mother's risk at 3 P.M. January 13, I saw the patient in her home at 5.30 P.M.; her rectal temperature was 99.4°, pulse 120, respiration 24.

January 14, at 10 A.M., the temperature was 99.4°, pulse 122, respiration 22, and at 5 P.M., temperature was 99.6°, pulse 124, and respiration 26. The patient had, in addition to the adrenalin in orange-juice, one teaspoonful of meat-juice at 11 A.M., 3 P.M., and 6 P.M.

January 15, the temperature, pulse, and respiration remained the same. Another teaspoonful of meat-juice and two ounces of a milk preparation was added to the nourishment.

January 17, the temperature rose to 101°, pulse 130, and the respiration 28. Two ounces of peptonized milk was added to the diet.

January 18, at 9 A.M., the temperature was 102.5° pulse 140, and respiration 28. Citrate of magnesi in three-ounce doses was given at 9 A.M., 9.30 A.M. and 10 A.M. At 12.30 P.M. there was a copiou evacuation of the bowels without any hemorrhage

An increased amount of peptonized milk wa added to the child's nourishment during the day At 4 P.M. the temperature was normal, and she wa permitted to sit up in bed for a half hour.

January 19, temperature normal, pulse 100, an respiration 22. Patient sat up for half the day Milk was given as follows: 4 ounces at 8.30, 4 ounce at 10.30, 4 ounces at 12.30, with one soft-boiled egg and 4 ounces at 6 P.M., with another soft-boiled egg

January 21, an increased amount of milk, togethe with thin beef soup was permitted. From this tim on, the temperature remained normal and the puls gradually came down to 85, and the respiration t 20, where things have remained stationary.

January 23, fish added to diet, and on Januar 25 a little chicken.

On January 31 the adrenalin was discontinue and the child permitted to walk on the street wit her parents. In another week she was allowed t play at pleasure with her child associates and to ea with the family.

At the present writing she eats and sleeps well apparently none the worse for her narrow escape and but for a slight anæmia, is as well as ever.

Careful search of medical literature by this write has failed to reveal a single case of the treatment o purpura hæmorrhagica with adrenal-gland prepara tions. The drug has heretofore been used ver largely in local hemorrhagic conditions, although number of reports of its use in intestinal hemorrhag during typhoid fever have been published. It i our opinion that in adrenal-gland preparation w have a certain and reliable constitutional hæmo static. And if this be true, it will readily beseen what a broad field is opened for its useful application

325 WEST FIFTY-FIFTH STREET.

## A STUDY OF A SCARLET-FEVER EPIDEMIC

BY ALFRED C. HAVEN, M.D.,
LAKE FOREST, ILL.

LAKE FOREST is Chicago's most aristocrati suburb. No town in the West can challenge her fo beauty, both natural and acquired. It is the sea of a university, the location of Chicago's most pre tentious country club, the Onwentsia; abounding i beautiful country homes of Chicago's millionaires, th grounds are acres in extent, and not suited to th spread of contagion. The town has twenty miles o paved roads, good sewerage system, including septic tank, water supply from Lake Michigan, an no expense has been spared to make it a mode suburb, with all the conveniences of a city combine with the attractions of the country. It is locate on a high bluff, intersected with deep ravines, an in the midst of an ancient forest of oaks. One would have looked for an epidemic almost anywhere els rather than in this beautiful sanitary spot. Th epidemic was peculiar in many respects, and a recita of its chief characteristics, I think, will be of interest The first case originated in November, 1902, in a lad who sold papers at the station; he was promptly removed to the isolation ward of Lake Forest Hospital, a modern cottage hospital built and equipped with every convenience, and a gift complete from Mrs. H. C. Durand. This first case was uneventful, except for a mild nephritis. Two or three cases per month were reported till February, 1903, when ten per week, and one week fifteen appeared. Then vigorous measures were adopted by the local Board of Health. The public and private schools, con

taining some 500 pupils, were ordered closed. The university was quarantined on its large grounds of sixty acres and allowed to remain open.

No children were allowed on the streets, all visiting was prohibited, all public gatherings in churches, Sunday schools, and lodges, and parties were positively interdicted. And, as an extra precaution, all stray dogs and cats were ordered shot on sight.

A house to house inspection was instituted. All sore throats were ordered reported to some physician. Every case was promptly isolated, the home placarded and the patient was not allowed to regain his liberty until all desquamation had ceased, ordinarily taking from four to six weeks, after which the place was thoroughly fumigated by formaldehyde gas and steam, by our own public disinfector, who was empowered to burn all mattresses and whatever else he deemed wise to destroy. All patients were transported in the hospital ambulance, which was thoroughly fumigated each time. A temporary auxiliary hospital was organized for scarlet fever, the mayor of the city loaning us his gardener's cottage, and two large additions thereto were hastily constructed. Trained nurses were secured. Also special police were sworn in to see that all regulations were obeyed.

Even with these rigorous measures, the epidemic persisted for two months longer, six altogether, and 108 cases were reported in a normal population of 3,400, which was greatly reduced by wholesale departures of families.

The cause of the epidemic seemed difficult to discover. Experts were consulted, the milk supply was investigated, with negative results. Representatives of both the State Board of Health and the Chicago Board of Health offered us valuable aid. It was noted early in the history of the epidemic that an unusual number of sore throats were prevalent; some of these were thoroughly characteristic of scarlatina, and others could not be distinguished from ordinary tonsillitis.

We recognized at once that these sore throats were really the manifestation of scarlet fever in immunes. No other symptoms of the disease appeared, but these cases were contagious, and were as dangerous to the community as any other cases of the disease. And when we could apprehend them they were isolated until all throat symptoms had disappeared. But, unfortunately, many of these cases never offered themselves for inspection, but scattered the disease right and left, wherever they wandered and expectorated. It soon became known that such cases were isolated, and poor, weak human nature was foolish or evil enough to conceal them. Free inspection was offered, but very rarely accepted.

These sore throats were the most prolific source of the spread of the contagion. Another cause of the extension of the epidemic was the fact that many of the cases were exceedingly mild. Often they deemed it almost persecution to be sent to bed, and, of course, some escaped.

Another peculiarity of the epidemic which served to spread the trouble was the unusual number of young adult cases. Most of our textbooks tell us that scarlet fever is peculiarly a disease of childhood, and generally infer safety after fifteen years of age, except in rare instances. But this was not our experience; fully one-third of all the cases were young adults over fifteen years of age, and no age up to forty seemed exempt.

One case was that of a professor in Lake Forest University, age forty. A typical case, high fever, brilliant efflorescence, angina, enlarged cervical glands, and most thorough desquamation. His case was associated with much mental depression.

Another patient was the Episcopal rector, aged thirty-eight. His two children and himself presented symptoms simultaneously, the children's were mild, his were quite severe, complicated with rheumatism and neuralgia. His desquamation was most vigorous. Great glove-like casts were exfoliated from both hands and feet. His recovery was uneventful, save that he slowly regained his strength. One adult, during the period of efflorescence and angina, chopped down a large tree and cut it into cord wood, and when captured later was visiting with a roomful of guests, who were drinking his health, as his marriage was appointed for a near day. This he was obliged to postpone, as he was brilliantly red with the punctate rash of scarlatina, and he acknowledged that two days previously he had had a "beastly" sore throat. Another case walked into my office with the rash in full bloom, a perfect picture of the disease. She had, as part of her duties, exercised a valuable dog on the streets for days, probably to the benefit of the dog, but I am doubtful as to the benefit derived by the community. Two adults undoubtedly owe the cause of the disease to their own carelessness; one deliberately entered the scarlet fever hospital, while delivering a package, and another, a young student, approached the hospital and laid two books on the window ledge and six days later joined his companions as a patient. I mention these cases, not only because they are interesting cases of adult scarlet fever, but also to show that they explain the spread of the epidemic.

Before they were aware of the nature of the disease they were suffering with, they passed it on to others, often deeming it merely an unusually aggravated sore throat.

Then, too, as the epidemic wore on, we repeatedly heard of indigestion (?) rashes, evanescent, not severe enough to call a physician, but probably adding their mite to swell the wave of contagion.

Cultures from throats were collected on sterilized blood serum and sent to Dr. J. W. Class of Chicago, who has made an extensive study of scarlatina, and who announces that he has discovered the specific germ of the disease, a giant diplococcus.

These were present in the specimens examined, although one interesting case, of which there was difficulty in diagnosis, did not show them early, but later gave typical results. Dr. Class believes his diplococcus to be pathognomonic; if so, the future diagnosis of scarlet fever will become far more scientific.

I do not see how scarlet fever and measles or rötheln are often confused. Scarlet fever is a much finer rash, more punctate, with small red spots separated, which later coalesce, and does not begin on the face. Measles has a much coarser exanthem and appears on the face first. There is difficulty with some forms of erythema in infants, due to digestive disorders. The high fever, vomiting and peculiar rash, are only suggestive of scarlatina. But a dose of calomel or castor oil and twenty-four hours' delay, usually clears up the diagnosis, as the erythema disappears, and the scarlatina persists. During the height of our epidemic, the daily papers of Chicago sought to dispute the diagnosis of scarlet fever, and invented a new disease which they christened "Philippine itch," claiming that the soldiers had imported it from our new colony to Ft. Sheridan, two miles from Lake Forest.

Our local board met this suggestion by inviting Dr. Geo. W. Webster, the President of the Illinois State Board of Health, and Dr. W. S. Christopher

of Chicago, to visit Lake Forest, and personally inspect the cases. They were both positive in their reports as to the disease being scarlatina and the Philippine itch bubble exploded. Surgeon Ives of Ft. Sheridan remarked that it was superlatively strange that this rare disease had escaped his observation. The mortality of our epidemic has been surprisingly small, only two deaths in 108 cases. One a feeble infant of three years of age, and one a young girl of sixteen, who, five years before, had had a typical case of scarlet fever, and severe nephritis; this second attack was moderately severe, but nephritis again developed with uræmia, convulsions and death, in spite of diuretics, salines, hypodermoclysis, heat, dry and moist, baths and packs. But the fact remains that the mortality was less than 2 per cent. We had some atypical cases, such as hyperpyrexia, delayed rash for four or five days. Some with hardly a trace of sore throat, and others severe anginas; some with brilliant rash, and some with only evanescent efflorescence. Some with only very moderate temperature. One, in whom no rash was ever discovered, who developed severe nephritis; a few that desquamated hardly perceptibly, and many so severely that the dried skin could be collected in handfuls. Enlarged cervical glands and otitis media, quinsy; one developed quinsy during the fifth week of the disease. Scarlatinal synovitis, rheumatism and neuralgias. One developed uræmia without a trace of albumin, the urine being reduced to eight or ten ounces in twenty-four hours, and other more common sequences were noted.

The epidemic vanished much more quickly than it appeared, and April 15 witnessed the last case. Severe measures were used, yet we feel the conditions warranted them, and that the abrupt termination was due to these measures, and we believe the thorough disinfection of homes will preclude a further visitation. The epidemic is already well-nigh forgotten and the annual hegira of Chicago summer visitors is taking place as usual.

---

## A PRELIMINARY REPORT ON SOME EXPERIMENTS WITH THE McGRAW ELASTIC LIGATURE.*

By M. S. KAKELS, M.D.

In the performance of a successful intestinal approximation the following requisites are essential: (1) Simplicity of application; (2) celerity; (3) uniform coaptation of peritoneal surfaces of the entire circumference of the approximated ends; (4) arrest of hemorrhage at point of approximation; (5) formation of a cicatrix that will contract as little as possible without being deleterious; (6) exact juxtaposition, as nearly as possible, of the histological structures; (7) the production of a minimum number of lesions.

Of all methods of intestinal anastomosis the Murphy button and suture seem to hold first place. Surgeons to-day seem to prefer these to all others. But do they include all these requisites? None of the methods up to the present time equal the ingenious device of McGraw's elastic ligature. Its advantage over all others is that (1) It is the simplest of all known methods. (2) It is the quickest of all operations for intestinal anastomosis. (3) There is a uniform coaptation of the peritoneal surfaces of the entire circumference of the approximated ends. (4) There is no incision of the bowel, and consequently no blood lost. (5) There is no escape of fæces, and therefore no exposure to peritoneal infection from bowel contents. (6) A cicatrix results that will not contract to a deleterious degree. (7) The operation, on account of its safety, is followed by a minimum of shock. (8) There is anastomosis by first intention. (9) There are but very few lesions made. (10) The bowel does not slough under the ligature, but undergoes a process of absorption in a few days without any raw surface whatsoever.

Besides these a very important fact is the advantage that the surgeon has in making the opening of any length he desires. These are McGraw's conclusions.

In order to verify the same I have made a number of experiments and have brought the specimens to show the results of the operation.

A number of dogs were taken. Seven gastroenterostomies and three enteroenterostomies were made. All the dogs survived except one which died from starvation and exhaustion at the end of the twentieth hour (an enteroenterostomy).

The dogs were killed by cyanide of potassium.

| | | | | | | |
|---|---|---|---|---|---|---|
| One | on the | third | day, or | 72 | hours | after (an enteroenterostomy) |
| " | " | fourth | " | 96 | " | " (gastroenterostomies) |
| Three | " | fifth | " | 120 | " | " |
| One | " | seventh | day, | 168 | " | " (a gastroenterostomy) |
| " | " | eighth | " | 192 | " | " (an enteroenterostomy) |

Two dogs upon which gastroenterostomy was performed on March 6 were still living on March 9.

In three cases only of the eight autopsies made did the ligature completely cut through. The round elastic ligature of 2 mm. thickness was taken in three enteroenterostomies and three gastroenterostomies. The ligature of 3 mm. thickness in two gastroenterostomies, and the ligature of 4 mm. thickness in two gastroenterostomies. The operation was performed exactly as described by McGraw. All aseptic precautions were taken and every case ran an afebrile course. No case developed sepsis or peritonitis, and after twenty-four hours the animals resumed their natural condition and showed no signs of distress whatsoever.

My conclusions thus far from these preliminary experiments are as follows:

1. For rapidity it is one of the quickest of all known methods. I made one anastomosis with the interrupted sutures within fifteen minutes. With the continuous sutures I am sure this time can be materially shortened.

2. There is no loss of blood except the slight amount produced by the Lembert sutures on the serous surfaces.

3. I found it as simple as, if not simpler than the Murphy button.

4. There is absolutely no escape of intestinal contents, and therefore no exposure to infection of the peritoneum from this source.

5. There is no shock, on account of short exposure and little handling of viscera.

6. There seems to be a uniform coaptation of peritoneal surfaces of the entire circumference of the approximated ends.

7. Very few lesions are made.

8. The bowel seems to have been cut through without sloughing.

McGraw states that three or four days is sufficient time to provide for a free opening.

Of the eight cases, in two upon which an autopsy was made (one on the third day and one on the fourth) there was only a partial cutting through, while in one (that examined on the eighth day, or 192 hours after an enteroenterostomy) and two gastroenterostomies examined on the fifth day, or 120 hours after, there was a complete opening and disappearance of ligature, while three gastroenterostomies show only a commencing severance.

The non-successful production of a complete

*Paper read and specimens presented before the Surgical Section of the New York Academy of Medicine.

opening in some of the cases I cannot ascribe to any faulty technique, as all the cases were operated upon in the method described by McGraw. The failure to cut through, from my experience in these few cases, I attribute, in the first place, to too thin a ligature, and, secondly, to a greater thickness of the dog's stomach and intestine than that of man. Perhaps in the human being a ligature of 2 mm. thickness will cut through in a shorter time than eight days.

If we look carefully at some of the specimens, it seems that only about ¼ inch of tissue was included in the ligatures, when, in fact, in no case was less than one inch taken. This was sufficient when we take into consideration the small lumen of the dog's intestine.

In conclusion, I would like to say that for man, in order to obtain a free opening within three or four days, it would be much safer to use a ligature of three or four mm. thickness, even if it makes a clumsy knot, and that we should not hesitate to take more than an inch and a half of tissue in the ligature (especially in gastroenterostomies), as I believe that the more tissue and the thicker the ligature, the more pressure will be brought to bear and the quicker will it cut through.

Finally, that this method, barring the disadvantages caused by its slow action in cutting through, is far superior to all others for simplicity, rapidity, and efficiency, admits of no doubt.

71 East Sixty-sixth Street.

## POISONING WITH A SMALL DOSE OF QUININE.*

By M. GOLTMAN, C.M., M.D.,
MEMPHIS, TENN.

In this section, where quinine is so largely given and often indiscriminately, the relation of the following case may be not without interest: In the early morning of October 7, 1902, I was called to the Gayosa Hotel to see C. M., aged thirty-five years, who is a traveling saleman and lives in New Orleans, La. There was nothing peculiar in the personal history, with the exception of an unusual susceptibility and reaction to quinine. Family history was negative. The evening before the patient had dined with a few friends at a leading restaurant, and not feeling satisfied about the freshness of one of the articles ingested, thought it well to take a mild purgative.

One of his friends offered a laxative pill which he knew to be efficacious. Being assured there was no quinine in the pill, the patient swallowed it. Within twenty minutes he felt a peculiar tingling sensation which he knew, from experience, to be due to the effects of quinine. The tingling was quickly followed by the appearance of large wheals in different parts of the body, which quickly coalesced. These wheals became redder and redder until they had a purplish appearance.

When I saw the patient he was swollen and unsightly, and his suffering required morphine, which soon, however, brought relief.

He then told me that he had yet to go through his worst experience, that the wheals would be converted into large "blisters," and that after the fluid from these would be absorbed the skin would peel off and leave his body raw and sore; that this process was always worse about the genitals, and he looked forward to what was in store for him with great dread.

The genitals were as yet free from wheals, at which the patient marvelled, and he begged me to exert my best endeavor to prevent their formation.

I prescribed a paste of zinc oxide, starch, bismuth, carbolic acid and lanolin, to be spread thickly over the body, with strychnine and morphine internally.

The next morning bullæ were forming over the affected parts, but the genitals remained unaffected.

On October 9 the bullous formation was marked, and in places the surfaces were already raw, just as the patient had predicted. The pulse was 112 to the minute, and the temperature 101½° F. Suffering was great and required morphine hypodermatically. I opened a great many bullæ at their lowest points, expelled their contents, but preserved the epidermis, and almost without exception, wherever I did this no rawness resulted. The genitals never became involved, and in a few days the patient was practically well. No other members of his family have this idiosyncrasy. Dr. William Krauss of this city saw the case with me and evinced much interest in it.

The condition was no doubt a toxic angioneurosis, and while I have many times seen urticaria after giving quinine, I never saw anything like this before, and never thought it possible for such to occur from such a cause. The question of food poisoning can, I think, be eliminated. Some of the single bullæ were as large as the palm of the hand. The hands, feet, and thighs were most affected, the fat especially being enormously swollen.

The dose of quinine must have been very small, because the pill swallowed was itself quite small.

In the Medical Record of April 4, 1903, I note the report of a case by Dr. Lewis Conner of almost fatal poisoning by six grains of quinine. In Dr. Conner's case the heart seemed to suffer most. In my case it was the skin. I recall a number of patients who cannot take quinine per os on account of the urticaria it produces, but who take it hypodermically without any such effect. I believe the urticaria in these cases is the result of gastric irritation and is not a toxic influence.

In the case here reported the same severe symptoms followed when oleate of quinine was rubbed into the skin several years ago during an attack of fever, thus showing that the condition is due to quinine intoxication. Other drugs, like phenacetin, belladonna, and morphine he stands as well as anybody.

## STRANGULATED OBLIQUE INGUINAL HERNIA IN A CHILD ELEVEN DAYS OLD; OPERATION.

By J. HUTCHINGS WHITE, M.D.,
MUSKOGEE, I. T.

I was engaged to take care of Mrs. W. during her confinement, which proved to be normal, a healthy, apparently normal child of eight pounds being born. Everything progressed favorably until the fifth day, when, during my visit, my attention was called to a "lump" in the child's right groin. Upon examination it proved to be a hernia. I set about to reduce this by applying taxis for a short time without anæsthesia. Being unsuccessful, chloroform was given and reduction easily effected. The hernia came down during a crying spell at 8 A.M. and was reduced at 11.30 A.M.

The necessary precautions to guard against a recurrence were taken and detail instructions were given nurse what to do with child during crying spells. Notwithstanding this, however, on the eleventh day I was called during the afternoon to

see the same child. The hernia had been down since 9 A.M. Taxis with and without chloroform and placing the child in an inverted position with flexed thigh all proved fruitless. Hot compresses were placed on the hernia and the child allowed to rest until evening. No vomiting occurred and, with the exception of being a little fretful, the child seemed rather free from pain.

During the evening I consulted with Dr. Frank M. Tiffany of Stamford, Conn., and again taxis was tried; this proving ineffectual we decided to operate. Herniotomy was performed at 10 P.M. We found a much congested gut, which was very blue. The use of hot applications, however, put new life into it. Reduction was effected, sac tied and cut off and abdomen closed. The little one's condition was critical for a few days, but he rallied and made a favorable and complete recovery.

Certainly this child's condition was critical, as proven by the condition of the gut, yet there was an absence of vomiting and very little pain. The conclusions are, therefore, that it is not always wise to wait for urgent symptoms, but in those cases in which it is impossible to reduce, under anæsthesia, a recent hernia, especially in young children, operation is indicated. Congestion is increased on standing, and gangrene may take place in one hour, or it may not take place for twenty-four hours.

This, I believe, is the youngest herniotomy case recorded. In England the records show a case in a child seventeen days old.

---

**A Bloodless Case of Placenta Prævia.**—N. G. Moore reports the case of a young woman who had had three miscarriages. A third pregnancy occurred, and the patient had intermittent bleeding of insignificant character. At the seventh month labor pains set in, and the presenting bag of waters seemed only slightly thickened. The sound of a bursting sac was heard, and on examination a half placenta, with about four inches of cord could be seen outside, and the head could be felt against the perineum. There was no hemorrhage, and the next pain delivered a living child. The other half of the placenta was found adherent to the os uteri, and was removed without difficulty, and with no hemorrhage. The patient made a perfect recovery. The author believes the case to be unique. His theory in explanation of the case is that there was a central implantation of the placenta, which, being thinner than usual, was sufficiently elastic to allow the small head to engage in the dilating os, where it acted as a stopper until the placenta ruptured, permitting the body to follow it until delivery was completed.—*St. Louis Courier of Medicine.*

**Rheumatism in Childhood.**—Alfred Friedlander inclines to the theory that the exciting cause of this disease belongs to the pyogenic group of bacteria. It is probable that in the majority of cases the tonsil is the primary seat of infection. Streptococci have recently been demonstrated in the peritonsillar tissue in rheumatism which is of importance as showing that infection may occur not only through the lymphatic circulation, but also through the general systemic circulation. In this light rheumatism may be regarded as a true septicæmia. The author discusses the differences in the clinical manifestations of rheumatism in children and in adults. Arthritis is at its minimum, endocarditis at its maximum in childhood; peliosis rheumatica is common, rheumatic nodules occur more often, and recurrent epistaxis is frequent. The administration of small doses of salicylates at intervals (say during one week each month) for long periods of time has been successful in many cases. But the therapy of rheumatism in childhood is not a matter of drugs alone. Proper clothing, regulation of exercise, avoidance of exposure, prevention of anæmia and attention to the condition of nutrition by the enforcement of a properly regulated diet will be found to be the most reliable aids in the management of a condition always troublesome and frequently serious.—*The Cleveland Medical Journal.*

**Acetone and Diacetic Acid as a Cause of Persistent Recurrent Vomiting of Children.**—Edward L. Pierson has, during the past year, carefully examined the urine of children suffering from cyclic vomiting and has in three cases found the diacetic acid present either just preceding or in the early stages of an attack. He has successfully prevented and aborted attacks by the administration of bicarbonate of soda dissolved in whey made from skim milk. In the case of a child who had vomited eighty-seven times in forty-four hours in one attack and fifty-two times in thirty-seven hours in a second attack, soda was given in ten-grain doses three times a day for three months. At the end of that time the customary symptoms of an attack appeared, including a certain recognized color and facies, a peevish state and sudden lack of appetite, with a rise in the temperature. The soda was immediately increased to over 100 grains a day, and the urine examined, but no diacetic acid was present, as the urine was very alkaline. The author believes that this would have been a genuine attack, if the soda had not been at once largely increased in amount. As to diet, when attacks are imminent, he puts the child at once on whey, which also acts as a diuretic, giving also a little scraped beef, and increases the soda to 125 grains in the twenty-four hours. This diet, with the soda, is kept up for two days, when the food is gradually increased, and the soda diminished.—*Archives of Pediatrics.*

**A Suggestion for the Treatment of Acute Sepsis.**—J. Wernitz believes that advance in the treatment of acute septic conditions is to be made not along the lines of serum therapy but through methods of stimulating elimination of toxins from the blood. Free action of the skin and kidneys is the object aimed at, but the customary means employed, viz., subcutaneous or intravenous infusion of saline solution, has several disadvantages. In septic processes the heart muscle is weakened and the rapid introduction of a large volume of fluid is apt to overwhelm it, producing a paralysis which may be permanent. The administrations of infusions is troublesome and painful, and the temptation is to give them less often but in dangerously large amounts. Owing to the complicated nature of the procedure, it is often postponed till a stage of the disease when it is too late to do good and is not without risk. The author recommends a form of colon irrigation which is very simple and can easily be carried out by the laity after a single demonstration by the physician. The patient is disturbed very little, and there is no danger of overtaxing the heart through too sudden introduction of fluid. An ordinary rectal tube is introduced into the rectum as far as possible without causing pain. It is connected with an irrigator containing one per cent. salt-solution and the fluid is allowed to flow very gently. As soon as peristalsis is excited the irrigator is lowered and the solution is allowed to flow back, usually bringing with it large amounts of fecal matter and accompanied by the expulsion of gas. This procedure is kept up until the intestine is thoroughly cleansed, the solution being replaced by fresh as often as necessary. As soon as the gut has been well cleansed it is ready for absorption, and similar irrigations may be given at hourly intervals, each irrigation taking about an hour. When the least discomfort or feeling of fulness is caused the irrigator is lowered or the current interrupted for a time. The results are speedily evident in a falling temperature, profuse diaphoresis and diuresis, less thirst, the skin and mucous membranes become moist, and the patient's general condition undergoes improvement. That this is due to the irrigations may be shown by omitting them and noting the return to the previous condition sure to occur.—*Volkmann's klinische Vorträge*, No. 352.

## THE PHYSIOLOGICAL ACTION, INDICATIONS, AND TECHNIQUE OF SALINE INFUSION.

DR. P. BERMBACH gives, in the *Sammlung klinischer Vorträge* (No. 350, 1903), a valuable résumé and critique of this question. The changes effected in the blood of animals by saline infusions resolve themselves into two stages, that of hydration, and that of reconcentration (with a third, relatively unimportant one, of return to the normal). The stage of hydræmia lasts, according to Biernacki, who injected subcutaneously, one to two days, the maximum being reached within twenty-four hours, and the normal being regained first on the fourth day. During this stage the organic matters are always infranormal, but always over 50 per cent. The diminution in the morphologic elements is always greater, but their regeneration is more rapid (Biernacki places the beginning of the increase of the red cells at four hours, and the duration of the increase at twenty hours). No matter how great the amount infused, the salinity never surpasses 0.4 per cent.

The stage of reconcentration lasts, according to Biernacki, one to two days. The water content and the white cells are reduced, while the red cells, hæmoglobin content, and the inorganic constituents of the blood. are above normal. On the fourth day the number of the red cells and the water content are again normal, but the specific gravity and the saline content are still above normal. The changes in the urine proceed parallel with those in the blood; the first one to two days, polyuria with a corresponding diminution of content and specific gravity, but an increase in the absolute amount of the solids; increase in chlorides, phosphates, and sulphates. The second or third day the amount decreases, to normal on the fourth. During this decrease the chlorides are absolutely and percentually decreased, some salt thus being retained in the organs and modifying excretion for six or seven days. Phosphates and sulphates also decrease, but the sulphates show a secondary rise when the urine returns to normal. Synchronously with this secondary rise twice on the third day, transient hæmoglobinuria was observed. Following intravenous injections of cultures of bacillus coli Bosc and Vedel observed hemorrhages into the intestines and kidneys, gastrointestinal disturbances, heart weakness, and fever; and they found that saline infusions promoted elimination by diuresis and cataphoresis, increased hæmogenic function, lessening of the globulicidal action of the pathogenic serum, and increased and heightened phagocyte action. But Dastre and Loye failed to save animals infected with splenic fever, glanders, bacillus pyogenes, and diphtheria toxin.

Therapeutically, infusions are now generally employed in cases of hemorrhage. We now know that death in such cases occurs from cardiac paralysis due to fighting a vacuum, so to speak. In this condition stimulants are without effect, while infusions almost immediately strengthen and slow the pulse and the respiration, raise the temperature, and soon effect striking improvement in the general condition. Schwarz injects 250 c.c. during one and one-half to two minutes, and then allows an interval, after which he repeats the injection, so that in twenty minutes 1 liter is introduced. Used for the relief of anæmia the effect is permanent, except when the anæmia is secondary to a deleterious underlying disease. The operation is devoid of danger, the few reported cases of death which followed some days later being clearly referable to the original disease. Mikulicz, however, recommends not to inject too much for fear of starting secondary hemorrhage. Infusions have been resorted to in cases of iodoform intoxication, and mercurial and carbonic oxide poisoning without clearly demonstrable favorable effects, they having, in most cases, been combined with venesection, which renders difficult the apportionment of the credit for the observed favorable influencing of the condition. In uræmia, however, some rather decided results have been attained, mostly along with diuresis. In the "typhoid state," even though diuresis should not occur, the pulse and general condition improve, the tongue cleans, and the temperature lowers. The place of infusions in the treatment of cholera is assured. Here, as the injections must be repeated ten or fifteen times during the stage of asphyxia, the intravenous method should be avoided for fear of phlebitis and consequent embolism. The site selected should be preferably the belly wall and the inner surfaces of the thighs, as the circulation in the extremities is poor or nil. Improvement is to be looked for only when the stage of asphyxia has lasted but a short time, and injections should be repeated a few seconds apart. The condition in cholera infantum being identical, many children that now die might undoubtedly be saved by infusion treatment.

The indications for infusions are then the necessity of replacing lost fluid, or bodily heat, or the removal of toxic substances. Bermbach adds, the prevention of toxic nephritis, the type being scarlatinal nephritis. In scarlatina infusions should be used as early as possible, from about the time of the fading of the rash, at intervals of four to five days, in quantities of $\frac{1}{100}$ to $\frac{1}{75}$ of the body weight. Enemata are quite commonly substituted for infusions, but this is wrong, as in many cases the absorptive power of the intestine is small or absent, and the entrance of the fluid into the vessels is consequently much slower than with infusions. Contraindications to infusions are the presence of infective foci liable to be discharged into the circulation by the operation. Sahli adds the presence of marked dropsy, cardiac insufficiency, cyanosis or pulmonary œdema; but with considerable dropsy one may infuse provided the heart muscle is tolerably competent, as with slight valvular lesions. Under these conditions,

however, constant observation of the patient (as during the administration of chloroform) is necessary.

Respecting the technique, the quantity depends upon the case; in acute anæmia Schwarz recommends 1.5-2 liters; Bischoff uses after hemorrhage 50-60 per cent. of the blood mass (2.7-3.24 liters), but Bermbach considers 1.5-2 liters sufficient, more being used later if necessary. The exact composition of the fluid does not so much matter; a much more important point is that it shall not injure the blood cells. The usual composition is 0.6 per cent. salt-solution alkalinized by two drops of sodium hydrate (or 0.1 per cent. of sodium carbonate) to the liter. The fluid must be freshly prepared, as it soon becomes moldy. The temperature should be 38-40°C., and it is of great importance that it remain constant throughout the whole of the operation. The necessary armamentarium consists of an irrigator (or a glass funnel) with tubes and a not too fine needle. The interior of the apparatus must be free from detachable particles which could become emboli. The respective merits of the intravascular and the intracellular routes are as follows: With the latter blood hydration takes place more gradually, Cohnheim having observed a dilution of only 6-7 per cent., and Biernacki one of only 2.79 per cent. after the infusion of 4.5 per cent. of the blood mass. When the danger is immediate, and the desideratum an instant effect, the intravascular route will naturally be selected. The intracellular method has the disadvantage that when absorption lags behind introduction, very painful water-boils form, whence the necessity for selecting the loosest subcutaneous tissue. To diminish the size of the boils Sahli injects simultaneously by five tubes, into the breast, belly, and thighs. In intracellular infusion there is always a blanching of the part, but this soon disappears if the pressure is not too great. Of the intravascular routes the intravenous should supplant the intraarterial, as the latter requires a preliminary dissection under an anæsthetic, besides involving other dangers (notably the use of greater pressure). The intravenous method is free from danger. The entrance of air must be avoided, but the imminence of this danger has been somewhat overrated. In all cases, intracellular and intravenous, but especially the latter, the pressure must be kept low (never more than 1 meter, and less in the intravenous method). High pressure is capable of doing great damage. Finally the necessity for rigorous asepsis need not be emphasized.

## THE PRESENT STATUS OF MÉNIÈRE'S DISEASE.

Upon the basis of a critical study of the literature, and of a personal observation of some fifty cases, Dr. Gustav Heermann reviews this subject *in extenso* in the *Sammlung zwangloser Abhandlungen*. The great variation in the symptomatology, and especially the facts that no definite uniformity of symptoms corresponds to a given set of lesions, and conversely that no uniformity of lesions answers to a given group of symptoms, go to show that the affection is not a pathological unity, but that it is merely a syndrome. Regarding the pathological changes present it may be said that the necropsy in persons who have exhibited Ménière's symptom complex, always reveals alterations in the ears (which alterations may have their seat in the labyrinth or in the middle ear), or in the auditory nerve and its nuclei, or the parts of the cerebrum adjacent to the ear, or in the cerebellum. With a view to clearness of conception, Heermann defines the affection as follows: "Ménière's symptom complex is the external expression of an irritation or a damaging which has at some point affected the central or peripheral elements of the organ of audition." The nature of the irritation, and the place at which it has operated, can frequently be determined directly, or can be inferred from the accompanying pathological findings. In some cases, however, we are not in a position to pronounce upon it. In its complete development Ménière's symptom complex includes the triune symptomatology of: Disturbances of equilibrium sickness (with or without vomiting), and entotic sensations. These symptoms may be present in their entirety, or as individuals, and in the most varying degrees of intensity. The intensity of the subjective disturbances does not depend upon the severity of the irritation or damage, but above all upon the bodily and psychical resistive power of the individual, which can be subject to great and even momentous fluctuations. Certainly, however, the functional disturbances which, other things equal, can be all the greater where an ear which has already suffered in its function, is concerned appear to be dependent upon the magnitude of the irritation and the place at which it operates. We are thus to consider as having Ménière's syndrome, all cases which present the above triune symptomatology. Whether or not apoplectiform attacks occur, matters not. There is no valid reason for separating the cases with them, and of the author's fifty cases, thirty showed them. Equally it matters not whether the symptoms mentioned possess only slight intensity; the case none the less falls in the present category. Considering the multiformity of facies of the cases, a uniformity of prognosis would naturally not be expected. The most favorable cases are those which present a fundamental removable lesion. The severity of the symptoms does not, in itself, warrant an unfavorable prognosis, and the same may be said as to the previous duration, as neither of these factors gives a clue to the location of the lesion. Still in the first attack the prognosis may be said to be doubtful; and when repeated attacks have occurred extreme reserve is necessary. The author goes quite thoroughly into the question of therapeutics. His experience warrants the conclusion that specialistic treatment alone only brings lasting results in rare cases, but that in combination with general measures directed toward the other pathological conditions present, it is capable of yielding satisfactory results. The keynote of successful treatment is the removal of the irritation, and to this the exact investigation of the ear is an indispensable prerequisite. It goes without saying that this includes thorough local treatment of the nose and throat, including all necessary operations, such as upon deflected septa, etc. The same is true as regards all digestive disturbances, especially constipation. During the

paroxysm the anxious patient who feels himself about to die, should be reassured; the vertigo combated by the recumbent position; if the patient feels as though he were about to fall out of bed the head should be turned toward the south side, and if as though the room were whirling round him, the eyes should be kept closed. Hypersensitiveness to sounds can be best combated by tamponing the ears with wadding moistened with glycerin. When thrown back upon the pharmacopœia, what can we do? As regards the numerous remedies in the literature, it usually happens that they acted in the one case reported, and when subjected to careful tests, prove valueless. Also many derive their warrant from the authority of some name, without having any real virtue, or even rational basis. Of this number is quinine, which was introduced by Charcot. This is a "very dangerous remedy, and from the standpoint of the otologist must be absolutely execrated." In the author's experience it never did any good, but repeatedly acted directly unfavoiably. The same is true of the salicylates. Electricity Heermann has tried, but he has never seen in it any certainty of favorable action. The bromides yielded no results. Sulfonal, however, in some cases worked "wonderfully" on the subjective entotic disturbances, and he places it in the first rank as a sedative. One of his cases took it almost daily for five years. Toward pilocarpine he avows himself not nearly so sceptical as toward quinine. It is, however, quite uncertain in its action. The results as regards function are often very satisfactory, though inconstant. Finally in the cases seen in caisson workers (in which the lesion is with the greatest probability to be sought in the brain) the treatment consists in restoring them to a compressed-air environment, under which condition the symptoms rapidly disappear, and then exercising great care in the graduation of the release.

---

## TEMPERANCE INSTRUCTION IN THE PUBLIC SCHOOLS.

A WORK has been published recently, which may be said to contain the latest scientific facts bearing upon physiological aspects of the liquor problem. The work consists of investigations made by and under the direction of W. O. Atwater, John S. Billings, R. H. Chittenden, and W. H. Welch, who composed the sub-committee of the committee of fifty to investigate the liquor problem. The report on the present method of instruction regarding the physiological action of alcohol is valuable and interesting, and throws much needed light upon the mode in which this form of instruction is carried on in many parts of the United States. The compilers of the report obtained their information from the following sources: First, standard textbooks in common use in colleges, universities, and medical schools. Second, letters received from prominent physiologists, both in this country and Europe, giving their opinions on this subject. Third, textbooks "indorsed and approved" by the "Department of Scientific Temperance Instruction" of the Woman's Christian Temperance Union for use in the public schools. Fourth, answers of public school-teachers in reply to questions as to fitness and value of the books and results of so-called "scientific" temperance instruction.

The mass of information thus gathered together has been arranged and dealt with by the authors in the above order. The first part of the report is taken up with a consideration of the various opinions held by physiologists and expressed in textbooks, upon the fundamental question of the food value of alcohol and its influence upon the processes and organs of digestion. This subject has been so frequently and so fully discussed of late that it will be of more general interest if the facts collected with regard to the public school textbooks are somewhat briefly surveyed. What is known as "scientific temperance instruction" was first introduced into the United States by Mrs. Mary H. Hunt in 1879, and has gained a strong foothold in the public-school curriculum throughout the country. "The true character of the movement," says the report, "is well set forth in one of the publications of the Woman's Christian Temperance Union," which runs as follows: "This is not a physiological but a temperance movement." In all grades below the high school this instruction should contain only physiology enough to make the hygiene of temperance and other laws of health intelligible. Temperance should be the chief and not the subordinate topic and should occupy at least one-fourth the space in textbooks for these grades." Laws drawn up with the view of carrying out the foregoing ideas have been enforced in almost every State of the Union, differing only in the relative stringency of their enactments. New York State has an especially stringent law. After a trial of fourteen years, public opinion in Massachusetts declared itself against more strenuous legislation, and the teachers and educators of that State expressed themselves in favor of a less exacting measure. The object of this general movement to inculcate habits of temperance among the rising generation of America is excellent, but the methods adopted to reach these ends are by no means so deserving of commendation. It is stated that, almost without exception, textbooks on physiology and hygiene in use in public schools are, when not trivial, misleading. The report quotes from a large number in order to drive home the truth of this assertion. It would seem indeed as if many of these books were written with the intention of so thoroughly frightening the younger children and of imbuing them with such a horror of alcohol, that they will decide not to use it under any circumstances. The report, however, points out that this object is likely to be defeated, on account of the natural reaction of healthy children, and especially of boys, to too highly colored statements of this nature.

As to the view taken by teachers with respect to the manner of teaching physiology in public schools, the answers received by the sub-committee in response to certain questions propounded tend to show that opinions more or less at variance with those favoring so-called scientific education are held by a majority of the teachers.

The conclusion come to by the sub-committee as regards "Scientific Temperance Instruction" is that under this name "there has been grafted upon the public school system of nearly all our States an educational scheme relating to alcohol which is neither

scientific, nor temperate, nor instructive. Failing to observe the distinction between the diametrically opposite conceptions of use and abuse, some of its advocates have not hesitated to teach our children that the terrible results of a prolonged abuse of alcohol may be expected to follow any departure from the strict rules of total abstinence. The success which has attended the efforts of the Woman's Christian Temperance Union to secure the desired legislation may be readily explained by the sympathy sure to be felt by all intelligent people for any sincere attempt to combat one of the most gigantic evils of modern times. There can be no doubt that the abuse of alcohol is a threat to our civilization, and any honest effort to diminish its consumption is certain to be welcomed without any very critical examination of the methods employed. That the originators of this educational scheme were honest in their intentions there is no reason to doubt, but they have violated sound principles of pedagogy in forcing subjects upon the attention of children at an age when their minds cannot possibly be adapted to comprehend them, and have shown themselves absolutely indifferent to the demoralization of our educational system resulting from forcing teachers to give instruction in a way which their experience has shown them to be ill adapted to accomplish the ends in view, and from compelling children to memorize statements sure to be contradicted by the experience of their later lives."

Regarded then from the view point of the scientist and the lover of accuracy in statement, it is to be regretted that if science be taught to children, it should not deal with absolute facts. The kind of scientific instruction which children are given in the public schools of the United States is intended rather as a means of fighting the curse of alcoholism than for the purpose of providing valuable mental pabulum. The ambition to check the evils of drink is a laudable one, but the methods adopted to reach this result are at least open to criticism.

---

### Medical Care of the Newfoundland Fishermen.

The *New York Post-Graduate*, in its July issue, calls attention to an article which appeared in the New York *Tribune*, June 12. The article in question treats of the medical and surgical service with which the Newfoundland and French fishermen on the Grand Banks are provided, and the lack of any such provision for the fishing fleet of the United States in the same waters. The result of this neglect being, says the *Tribune*, that "the fishermen of this country have to depend on the ministrations of the medical services of their rivals, or else suffer great loss of time from business in landing to place sick men under proper care." The British established the Newfoundland Medical Mission, which has three hospitals, one on the French shore and two on the Labrador coast, each with a resident doctor, a trained nurse, a staff of assistants from neighboring districts, and a steam launch for conveyance of patients. Lord Strathcona, too, has presented the mission with a steamer of 600 tons which cruises every season from the Grand Banks to Hudson. The Superintendent of the mission is Dr. Grenfell, who treats all who come to him for aid regardless of race or class or condition. Twenty thousand dollars a year are spent in this mission. There were 110 house-patients during 1902, and more than 2,600 out-patients.

The hospital service for the French fishermen was established in 1899, by the Société des Ouvres de Mer. The first vessel fitted out was lost, but in 1901 the French fisheries secured a steamer of 720 tons, 300 horse power and 10 knots an hour speed. This vessel is splendidly equipped for the purpose and is an ideal hospital ship. She has beds for thirty-six persons, including two physicians, four male nurses, and a priest. The work performed by both the British and French medical services has been splendid, and its value hardly to be gauged at its true worth. The *Post-Graduate* says: "Both the British and French missions are maintained by private associations and both are aided by Government grants. Certainly the United States should not be behind in this very important matter. The attention of the President and Congress ought to be brought to it. If we are the first nation of the world we cannot afford to be behindhand in such a benevolent enterprise as this.

The fishery is regarded as a training school for sailors, and on this ground alone the United States ought to do its share toward preserving their health and lives." With the preceding sentiments we are in complete accord. It is not right that a country so great and rich as this is, should overlook its manifest duty toward a deserving class of citizens like the brave and hardy fishermen. Furthermore, the position is derogatory for the United States to have to rely for medical aid on the charity of foreign nations.

---

### Gout in the United States.

Gout is generally supposed to be of rare occurrence in the United States. Nearly all the writers of textbooks on medicine, both American and British, state that the inhabitants of this country and Canada appear to possess a considerable degree of immunity from gout. Those who take this comforting view of the matter will, by reading an article in the July *Practitioner*, receive a somewhat severe shock. The number to which reference is made is given over to a symposium on gout, contributed to by many of the best known British authorities. The first article, however, is written by Mr. Thomas B. Futcher, M.B., Associate Professor of Medicine at the Johns Hopkins Medical School, and is entitled the "Occurrence of Gout in the United States." The authors oppose the popular belief that the disease is rarely met with on this side of the Atlantic and demonstrates its fallacy by convincing statistics. He says there is no question but that the malady is much more prevalent here than physicians suppose, and he holds that the failure on the part of medical men to recognize the condition is chiefly responsible for the notion that gout does not frequently attack Americans. Mr. Futcher is of the opinion that "the best method of determining the relative frequency of the disease in the United States as compared with Southern England, where cases are more numerous than in any other part of the world, is to compare the number of cases admitted to a general hospital in a large American city with the number of cases admitted to a similar institution in London. Thus, for the first fourteen years since the Johns Hopkins Hospital was opened, there were forty-one cases of gout admitted to Dr. Osler's wards, out of a total of 15,697 medical admissions, or, in other words, 0.26 per cent. of the cases. For a similar period of fourteen years, there were admitted to the medical wards of St. Bartholomew's Hospital, London, out of a total

of 33,356 admissions, or 0.37 per cent. of the medical admissions. That is, in London, the home of gout, the cases are a little less than one-third more frequent than they are in Baltimore."

As to the nationality of the victims of gout admitted to Johns Hopkins Hospital, 32 of the 42 patients were native-born Americans, 5 were born in Germany, 3 in Ireland, and 1 each in Canada and Finland. The negro, according to Mr. Futcher, would seem to possess a relative immunity. All the patients who were admitted in the period of fourteen years to the Johns Hopkins Hospital were, with one exception, whites. If then the statistics gathered in Baltimore are to be considered as representing more or less accurately the situation as regards the occurrence of gout throughout the United States, the conclusion is reached that the idea so long prevalent that the affection is rare in this country must be set aside as a mistaken one. Mr. Futcher emphasizes the point that the cause of this erroneous belief is the failure on the part of the medical profession to recognize the malady. The affection is usually confounded with rheumatism.

### Results of Vaginal Hysterectomy for Cancer.

In the *Transactions of the Mississipi Valley Medical Association* for 1902, Dr. Emory Lanphear gives the results of 362 cases in his own practice, and those of "263 other cures by 76 operators in the Mississippi Valley." And he adds some statistics. The population of the valley being 41,113,000, and that of New York and Pennsylvania 13,500,000, the census reports show only 679 deaths from cancer in the former territory, as against 1,101 in the latter. This is not explicable as due to a greater frequency of cancer in New York and Pennsylvania. For cancers of the breast (which are always operated upon), those of the stomach (which are never operated upon), and those of the uterus (which are operated upon in the West but not in the East), compare as follows:

| | Deaths from breast cancer. | Deaths from stomach cancer. | Deaths from uterine cancer. |
|---|---|---|---|
| Miss. Valley... | 874 | 3776 | 679 |
| N. Y. and Pa. | 613 | 1785 | 1101 |

The greater mortality in the less populous area applies then only to carcinoma uteri. The greater frequency of hysterectomy in the West must then result in: (*a*) a large proportion of cures; (*b*) a large proportion of post-operative deaths credited in statistics to shock, etc., instead of cancer; or (*c*) recurrences elsewhere. To determine the magnitude of the first factor, letters were sent to 200 operators in the valley, requesting the number of non-recurrences five years after operation for undoubted carcinoma uteri. A large number could report no cures, but 78 operators reported 291 cases free after five years. In most instances the diagnosis had been confirmed by microscopical examination.

Lanphear's own series comprised 362 cases. Faithful efforts were made to follow up the patients after operation, but they were, of course, not entirely successful. It was, however, known that one-fourth died of recurrence, and if the facts were available it is probable that one-third would be found to have died from internal cancer. More than a hundred, however, survived over three years, and it is definitely known that twenty-eight remained free from recurrence after five years. Moreover, a large number of later cases promise even better results. These statistics lead Dr. Lanphear to make a strong plea for the operation, and a somewhat unflattering comparison between certain sections of the country which shall be nameless.

---

### The Habits of the Yellow-Fever Mosquito.

Drs. Parker, Beyer, and Pothier, give in Bulletin 13 of the Yellow Fever Institute (Government Printing Office, 1903) the results of their studies of the yellow-fever question at Vera Cruz. Since 1509, when a Spanish command of 780 men lost there 720 men within fifteen months (400 in the first few days), the city has probably never been free from yellow fever, the yearly mortality since 1866 having ranged between 747 and 2. The sewerage is primitive, each house having its cesspool. All fluids from the houses drain along an open gutter with a fall of but four feet to the Gulf. Many of the older houses have cisterns exposed or loosely covered with boards, but the great majority of the people, especially the poor, catch rain water in barrels, or keep water brought from the public taps uncovered around the house. The mosquito *Stegomyia fasciata*, being a purely domestic form, finds natural breeding places in these vessels, and examination invariably revealed several to many thousand larvæ in every uncovered receptacle. This species is probably more widely distributed than any other throughout the tropics and up into the temperate zone. Formerly supposed to be a coast form, it has spread inward along lines of commercial communication wherever it has found a breeding place. Broadly speaking, this is the house or city which, during the time of the insect's flight (March to November on the Gulf Coast) stores its water supply in unprotected receptacles. These conditions supplied, even supposing the insect once exterminated, it is only a question of time till commerce reintroduces it. Though formerly none of our coast cities was exempt from yellow fever, improved sanitary science has pushed the disease beyond our borders. Still our "infectible territory" comprises all the region from Charleston to the Mexican border (all the region, that is, where stegomyia finds its natural breeding places), and inward from these centers of distribution along the lines of railroad and water communication. In Mexico this form of mosquito has actually followed two railroads to altitudes of 3,000 and 4,500 feet, and simultaneously yellow fever has accompanied it into the new ground. The authors found the mosquitos breeding on one schooner, and the adult forms on a number of iron ships. No larvæ were, however, found, and their transfer on iron ships is regarded as rare. But sailing vessels almost always afford opportunity for the females to deposit eggs, in the way of water stored somewhere on deck, and two or three females will infect the vessel. The development of the larvæ and pupæ appears, however, to be inhibited by the constant agitation of the water. The insect deposits from 40 to 150 eggs, which mature in ten to twelve days. If the water in which the larvæ and pupæ live be agitated the insects immediately scurry to the bottom, so that nearly all the water can be dipped out without getting any insects. Indeed, the barrel may be turned on its side and 80 per cent. will remain in the last few ounces of water. Therefore the last few ounces should be kerosened. But the larvæ are as quickly killed by being emptied on to the ground. Stegomyia is a day flyer, with a characteristic insidiousness and pertinacity in attack. Infection is aided also by the fact that the inhabitants of Vera Cruz devote from noon to two P.M. to the siesta, and by the absence of nets, the bite of the mosquito not causing troublesome irritation. The hands, face,

and ankles (unprotected by the low shoes and thin socks) are the principal places bitten. While many foreigners and better class Mexicans succumb, the principal fuel is the mountain Indian who lodges in the street or in large boarding-houses, which are rarely free from infection (one contributed seventeen deaths to the monthly quota of fifty-three).

## News of the Week.

**Victims of the Alps.**—The "playground of Europe," as the Alpine region has been called, is annually the graveyard of many adventuresome tourists. This year the death roll has been even above the average, for already there have been recorded more than three hundred accidents resulting in the death of one hundred and fifty visitors. The causes of this unprecedentedly large number of accidents have been two—cold and stormy weather and the foolhardiness of attempting dangerous ascents without guides. In addition to the loss of life from accidents, not a few deaths occur, according to Professor Zangger of Zürich, from cardiac thrombosis and pulmonary embolism in elderly persons who avail themselves of the supposedly safe means of reaching great altitudes afforded by the railways.

**Röntgen Ray Injuries.**—Numerous instances have been reported recently in both the medical and the lay press of serious and even fatal *x*-ray dermatitis. One of Edison's laboratory assistants has suffered in this way, and two members of the medical staff of the London Hospital were compelled for the same reason to give up their work in radiotherapy. The death of Dr. Blacker is recalled by the announcement that his widow has been granted a pension of £120 by the not too grateful British Government. It will be remembered that Dr. Blacker was reported to have acquired *x*-ray dermatitis of the arm while treating King Edward for rodent ulcer. The King was cured but the doctor died, a malignant growth supervening upon the dermatitis and advancing so rapidly as to baffle the therapeutic endeavors of Sir Frederick Treves and others.

**The Latest Weapon Directed against the Much Hunted Mosquito** is the *x*-ray. A Newark, N. J., physician announces that the Röntgen ray traversing the body of one of the *Culicidæ* will at once convert it into a harmless corpse. It is not said whether one must catch the mosquito and hold him in the track of the rays, or whether a simple announcement that a machine is in operation will suffice to bring the victims without further invitation.

**Chinese Barred from Mexico.**—The Mexican Government has issued an order prohibiting Chinese immigrants from landing on the west coast of the country and at ports in the Gulf of California. The reason given for this order of exclusion is the danger of the importation of plague

**A Plague of Dogs at Molokai.**—It has been the custom hitherto to allow the lepers at Molokai to take their dogs with them in exile, and as a result of this permission there are now about five thousand four-footed colonists, or five times as many dogs as lepers. The expense of feeding this great herd of animals is greater than that of providing for the lepers, and the Board of Health has therefore ordered that most of the dogs must be killed, but each leper will be permitted to retain one.

**New Gift to the Eye and Ear Infirmary.**—Dr. Richard H. Derby of the board of directors of the New York Eye and Ear Infirmary announces that the daughters of the late William C. Schermerhorn have supplemented their father's gift to the hospital of a building for an ophthalmic ward by providing for the complete furnishing and surgical equipment of the new building.

**Dr R. Melville Cramer** of this city was painfully injured on August 9 in a stage coach accident in the Thunder Mountain district of Utah. Accompanied by three other travelers and a guide, he was journeying to the Thunder Mountain gold fields, and when some distance up the mountain the stage was overturned by a snowslide and rolled down the hillside for nearly a mile. One of the party was killed, another suffered a fractured arm, and Dr. Cramer was badly bruised, but fortunately escaped fatal injuries.

**Ankylostomiasis in Germany.**—It is stated that the efforts of the German health authorities to check ankylostomiasis among the mine operatives in the Essen district have proved unsuccessful. The latest reports indicate that the disease is spreading. Its presence has just been discovered in the collieries of Franziska and Bergmann, in the middle of the Ruhr region, which hitherto has been exempted from the disease.

**An Alleged Cure for Tetanus.**—The daily papers announce that a Chicago physician has cured a boy in the midst of the most violent tetanic spasms by "an entirely venous injection of salts, chloride, and potassium, made in the lower arm."

**A Medical Pole Seeker.**—Dr. Jean Charcot, son of the late Dr. J. M. Charcot, has organized an expedition of antartic discovery which sailed a few days ago from Havre. The vessel carrying the party, called the *Français*, will make stops at Madeira, Buenos Aires, and Punta Arenas in the Strait of Magellan, and from this point will proceed to the antartic regions.

**Antiseptic Barbers.**—Under the new law of this State all barbers must be licensed and must conduct their business under certain rules of antiseptic treatment of implements. These rules forbid the use of powder puff, enforce that of clean towels, and require treatment of razors, scissors, and clippers with boiling water. About 15,000 barbers have registered in this city and have received their license. The penalty of practising without a license is $25 for the first offence and possibly imprisonment for from ten days to three months.

**The Medical Directory of the City of New York for 1903,** published by the Medical Society of the County of New York, has made its annual appearance. Among the changes made in this edition is the incorporation of the list of members of the Kings County Society with the general list of registered physicians in Brooklyn Borough. This is a most commendable change and we hope the list of physicians practising in Manhattan and The Bronx will be similarly amalgamated in the next edition. There is no advantage in publishing two lists of practitioners in the same city, and it sorely tries the patience of one who chances to turn to the wrong list in searching for a name. In this we disagree with the editor of the directory who commends himself for having retained a double list of Manhattan doctors. There are the usual lists of physicians in New York State, New Jersey, and Connecticut, street lists of physicians and pharmacists in Manhattan and Brooklyn, and miscellaneous information.

**Obituary Notes.**—Dr. W. S. PLAYFAIR, the well-known obstetrician and gynecologist, died at St. Andrews, Scotland, on August 13. He was born in 1836, his father being Inspector General of Hospitals in Bengal. He was educated at St. Andrew's and Edinburgh, taking his M.D. at the latter university in 1856. He entered the Bengal

medical service, serving in Oude during the mutiny, and also serving as professor of surgery in the Medical College at Calcutta. Because of ill-health he was obliged to leave India, and in 1863 began practice in London as an obstetric physician, being attached to King's College Hospital. For twenty-five years he was Professor of Obstetric Medicine in King's College, retiring in 1898, after which he was consulting physician to the General Lying-in Hospital and to the Evalina Hospital for Children. He was the author of many works and journal articles on gynecology and obstetrics. He was a Fellow of the Royal College of Physicians of London and of the Royal College of Surgeons of Edinburgh, as well as an LL.D. of St. Andrews. He served as physician-accoucheur to the Dutchess of Saxe-Coburg and Gotha (Dutchess of Edinburgh), to the Dutchess of Connaught, and to the Crown Princess of Roumania. He was a brother of Lord Playfair and Sir Lambert Playfair. In 1896 Dr. Playfair was sued by a woman for divulging certain facts reflecting upon her character which he had learned while she was under his professional care. At the trial the question of the truth or falsity of the charges was not considered, and the jury found for the plaintiff, awarding her damages to the unprecedented amount of $60,000. The decision established the principle that a physician was not justified under any circumstances in revealing a professional secret, and if he did so it was at his own peril.

Dr. JANNAT ERNESTINE HILLS died at the Willard State Hospital, New York, on July 11, 1903. She had been a member of the medical staff of the hospital since November, 1895. She was born in Auburn, N. Y., in 1861, and was a graduate of the Women's Medical College of Pennsylvania in 1893. After graduating she was for fourteen months an interne at the Sheltering Arms Hospital in Philadelphia, and was afterward on the staff of the New York City Asylum for the Insane at Hart's Island. Dr. Hills was a member of the Seneca County Medical Association and of the New York State Medical Association.

Dr. JOHN GLEISES of this city died on August 14, at his country place at Brookside, near Saratoga. He was fifty years of age and was graduated from the Bellevue Hospital Medical School in the class of 1877.

Dr. MICHAEL F. MCGRATH died on August 11, at Fishkill Landing, N. Y., of pulmonary tuberculosis. He was thirty-five years old and was a graduate of the College of Physicians and Surgeons, New York.

Dr. CHARLES JOHN GARITEE died in Philadelphia, on August 12, at the age of thirty years. He was graduated from the Medical Department of the University of Pennsylvania in 1894 and became a resident physician in the Episcopal Hospital. Death resulted from septicæmia.

Dr. FRANCIS M. POWELL died in Chicago August 16, at the Mercy Hospital, after an operation. He was born fifty-five years ago, and was graduated from the Starling Medical College, Columbus, Ohio, in 1875. He was for twenty-two years superintendent of the State Institution for Feeble-Minded Children at Glenwood, Ia., and was the author of many medical textbooks.

Dr. J. MUIR CORBETT, of Glasgow, surgeon on the steamship *Astoria* of the Anchor Line, was drowned, probably on August 13. He was last seen on that day, and his body was found in the North River at the foot of Fifty-second Street on August 19, after his ship had sailed without him. He was formerly a minister of the Scotch Church.

# Correspondence.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

ROYAL VISITS TO THE HOSPITALS—PRINCE OF WALES—HENRY VAUGHAN, POET AND DOCTOR—ASYLUM NURSING—AMALGAMATION OF HOSPITALS—ST. BARTHOLOMEW'S INQUIRY—MR. HUTCHINSON—CAMBRIDGE UNIVERSITY—PHARMACEUTICAL CONFERENCE—SMALLPOX—LONDON MORTALITY.

LONDON, July 31, 1903.

THE royal tour through Ireland—a veritable triumph—has been marked by the great interest evinced by both the King and the Queen in hospitals and the medical profession. In Dublin the University, Colleges of Physicians and Surgeons, and other corporations presented addresses and received recognition. Hospitals were also visited. In Belfast the new Royal Victoria Hospital, erected in memory of the late Queen was formally opened by the King, with whom was the Queen. Every possible honor was paid to their majesties by the public as well as the officials—in fact, it is said, Belfast was determined to eclipse Dublin in its manifestations of loyalty. This splendid hospital occupies a site of six acres, and contains every modern device for the benefit of patients and the promotion of medical education. The corridor is over a quarter of a mile long, and from it open eighteen wards, nine medical, nine surgical, while a nineteenth at the end is for ophthalmic cases. Taking the place of the older building this new hospital may be said to be the oldest charity in the Province of Ulster. On arrival at Londonderry, one of the first visits of their majesties was to the infirmary, where the address presented expressed gratitude for the support abundantly given to the efforts to combat disease, and the King, in reply, declared it afforded him "great gratification to be, in any way, instrumental in promoting the interests of such institutions." A memorial stone was laid by the King, and their majesties visited all the wards and chatted with many of the patients.

While so many doctors are in South Wales (Siluria), it is interesting to observe that a little volume has just appeared containing the prose works of a doctor, of long ago, and who has, though very late, won a place among English poets—Henry Vaughan, born 1621, died 1695. The Oxford University Press will shortly publish his poems. Meanwhile we have this little contribution of antique, but modern sounding prose. Vaughan was a considerable scholar, a philosopher, a patriot, a churchman, a loyalist, and, withal, a physician. He took part in the Civil War, and when his cause was lost retired to his loved Silurian hills and practised as a doctor while he gave his spare time to the muses. The little volume before me contains the "Mount of Olives," including the "Man in Darkness, or a Discourse on Death," and the "Life of St. Paulinus, Bishop of Nola." These works have only been reprinted once during the 250 years that have passed since he wrote them. But with this and the poems the silurist doctor will become known to this generation. If you like George Herbert or Sir Thomas Browne, look into Henry Vaughan.

At the annual meeting of the Medico-Psychological Association, a paper was read on "Female Nursing of the Male Insane." The author, Dr. A. R. Turnbull, described a visit he had made in company with Sir John Sibbald, Dr Fraser, and Dr. Robertson to the Meerenberg Asylum, near Haarlem, and the Wilhemina Hospital, Amsterdam. The former provides for 1,300 lunatics, of whom 600 are males. The staff consists of 57 females and 46 males. Two wards for restless cases were served by males only, but in all the other male wards the staff was mixed male and female. Dr. Turnbull narrated the details of the administration and working. The Wilhemina Hospital has a block for medical cases, another for surgical, and a third for mental, male and female cases. The restless cases are nursed by men and there are a few small rooms for noisy or violent patients. Dr. Turnbull said he had adopted the plan, to some extent, at the Fife and Kinross Asylum, and with results which induced him to advocate its extension. The president of the association, Dr. Ernest W. White, said he had employed a few female nurses in the male sick room of his asylum, and intended to extend the plan. Dr. Rob. Jones thought the presence of females had a soothing influence on sick lunatics, who would become restless under male nursing. Dr. Thompson of the Norwich Asylum disapproved altogether of employing female nurses in the male wards of lunatic asylums. He regarded the plan as undesirable from an administrative point of view, not to mention decency. There was some further discussion. The mere suggestion shows how, of late, female nursing has been pushed into every possible opening. Personally, I agree with Dr. Thompson, and with no little experience

of male nursing, cannot but regret that any one should propose to supersede them in the male wards of lunatic asylums. Any one conversant with lunatics, would I should have thought, refused to make the experiment. The fact is, that in England the self-appointed advocates of nursing as a woman's profession have been too energetic, and have found in some sections of the press a good deal of encouragement and maudlin nonsense. Consequently, male nursing has been at a discount and our surgeons have mistrusted it, even in cases in which common decency demands it. Our hospitals, too, are to blame in this matter. Hardly any of them train men to the work. The female staff have too much influence.

I do not feel at all sure that amalgamation of hospitals will come off as easily as was supposed, although the influence of the King's Fund is very great. The newspapers announced lately that the amalgamation of the orthopœdic hospitals was decided on. That statement is premature. The principal may be admitted, but the details must offer many difficulties. The site bought by the Royal will have to be disposed of, the enlargement of the National completed, and the union of the managing authorities arranged. Some must resign or be left out, the chairman of the Royal, Mr. Marks, for example, who, after his recent appearance in the law courts and the remarks of the judge, would have done well to retire. The staff of the amalgamated hospital could not but offer other difficulties, especially since the questions that have arisen at the Royal where the senior has been practically dismissed, as is believed illegally, and where other things have been done in defiance of the by-laws. Another danger is, that any attempt to force the matter may lead to the establishment of another hospital by a section of the governors. Then again, the question suggests itself whether the King's Fund—raised to support all the hospitals—is justified in devoting a considerable sum to promote the amalgamation. I doubt it. In this case the amount seems too large to spend in this way, and the result is by no means certain to prove satisfactory.

Over the managers. A good example of this occurred years ago at the London Hospital, which is always urgently crying out for money. A deputation waited on the committee with a proposal from the late Miss Hamilton to endow a men's ward, to be nursed by men, and made a training school for male nurses. The committee hesitated until they had consulted their matron, and then declined and, of course, lost the money.

The Mansion House Committee appointed to inquire into St. Bartholomew's Hospital has issued its report, which is altogether in favor of the proposal to remain on the present site. It is recommended to rebuild by degrees, as the money comes in. The committee consider that the hospital authorities are fully justified in appealing to the public for funds, and they are of the opinion that the administration has been conducted by the governors in a wise and enlightened spirit, with a due regard to economy, and in the best interests of the patients. A statement of the committee's proceedings and of the evidence taken is attached to the report. After this we may take it for granted that "Old Bart's" will remain in its present position and will gradually be converted into New Bart's, and become equipped with everything necessary to maintain its great reputation.

On the 23d ult. some of Mr. Hutchinson's friends gave him a complimentary dinner on the occasion of his seventy-fifth birthday. As a clinical observer and industrious accumulator of facts, this many-sided surgeon has always had numerous admirers, and the dinner was, therefore, bound to be a success. His London Hospital colleagues were not present in full force. Perhaps some had started for their holidays. In replying to the toast of the occasion, Mr Hutchinson spoke of his early training among the Quakers, to which he was indebted. It laid the foundation of his work since, and inspired him with a desire to see the truth of every question, to seek facts rather than theory. He also alluded to the question of leprosy, and expressed his pity for the lepers confined on Robin's Island for no fault or crime against society, and, in his opinion, without any necessity for such imprisonment.

Cambridge University has at last elected a professor of surgery. Mr. Howard Marsh takes the chair which has been left vacant since the death of Sir George M. Humphrey in 1896.

The Pharmaceutical Congress is being held at Bristol. The president, Mr. Idris, F.C.S., in his opening address said they were anxious for further restrictions in the sale of poisons. He held that the public needed more protection in the system of death certification. He also emphatically pronounced in favor of separating dispensing from prescribing.

Quite an epidemic of smallpox has been going on for some little time at Cambridge. At first it was held to be so slight as to call for no notice, except by the medical officer of health. But above one hundred cases have altogether occurred, with several deaths.

The mortality of London was, last week, lower than for many years. There were 513 fewer deaths than the average of the corresponding week for ten years. The annual rate per 1,000, which has been 13.9, 13.3, and 13 in the preceding three weeks, fell to 12.7 in comparison with 16.9, the average for the decade. In Greater London there were 679 fewer deaths registered than usual.

## INJECTION OF PARAFFIN OF HIGH MELTING POINT.

To the Editor of the Medical Record:

Sir: My attention has just been called to the paper by Drs. Hurd and Holden in your issue of July 11, in which they report a case of blindness following the injection of paraffin into the nose. I have recently become acquainted with the work of Dr. H. Eckstein of Berlin in this field, have seen several of his operations and operated cases, read his publications, and had the method demonstrated in some detail. I am much impressed with the results and with the care with which the method has been worked out to meet the indications, and to avoid complications. Dr. Eckstein has practised the subcutaneous injection of melted paraffin about a thousand times, and attributes his immunity from serious accidents almost entirely to the use of paraffin of high melting point, which, of course, solidifies more quickly and becomes harder. For the face, paraffin melting at 58 C. (136° F.) is used, but in other situations, one melting at 50° (122° F.) is sometimes employed.

This hard paraffin has the further advantage, as has been proved by clinical experience and by experiments on rabbits, that it does not soften, or become dislocated or absorbed; it may also be removed if desirable. The injection is made at a temperature about 10° C. above the melting point, and this is well tolerated by the tissues. Paraffin has so many advantages over vaselin, and the high melting point over the lower, that almost the only argument brought forward against it, is the difficulty of keeping it fluid during the injection. The technical difficulties have, however, been mastered by Dr. Eckstein in a very simple way, which I hope later to describe in detail, and he operates quite without fear of evil consequences.

Henry Ling Taylor, M.D.

Berlin, August 6, 1903.

## Progress of Medical Science.

*Boston Medical and Surgical Journal, August 13, 1903.*

**The Present State of the Surgery of the Prostate Gland.**—Paul Thorndike reviews the subject of prostatic hypertrophy and its treatment. He advises a resort to palliative measures when the condition is not so far advanced as to preclude any advantageous results from such procedures. For all those cases in which palliation is no longer possible his choice of operation would always be prostatectomy, in the absence of contraindications. The conclusions which he formulates are: (1) No prostatic should be allowed to suffer from lack of proper treatment. (2) There is still a place for the catheter in such treatment, and many patients can be made comfortable and can be kept so by its systematic and proper use. (3) All those who cannot be kept comfortable by palliative measures are fit subjects for some operation. (4) An operation is indicated immediately the inadequacy of palliative treatment becomes apparent. (5) The operation of choice is always prostatectomy, but patients over sixty or sixty-five years of age are rarely, owing to their lowered general condition, suitable objects for such a radical procedure. (6) To such as are not fit subjects for prostatectomy, the Bottini operation may be offered as one attended with little risk to life, followed by a short convalescence, and offering a fair promise of such a degree of improvement as will at least obviate any further necessity for the systematic use of the catheter.

**Five Cases of Renal Decapsulation.**—J. Bapst Blake presents a preliminary report of five cases of renal decapsulation performed in one of the services of the Boston City Hospital during a period of nine months. A final report upon the condition of these patients at the end of two years after operation is promised, but for the present only what may be called the immediate results can be recorded. The operation in each case was performed by two surgeons simultaneously, one decapsulating the right, the other the left kidney. The time of the operation was thus reduced by nearly one-half, and the patient did not appear to suffer from a noticeably increased amount of shock. In two cases the patients became cyanosed and suffered from a certain

degree of collapse on the table. This was thought to be due to interference with respiration caused by the pressure of the two large pads high up in the epigastrium, for there was no post-operative shock in these two cases. There was no marked increase of pre-existing renal elements of the urinary sediment following the operation. Red corpuscles were invariably present afterward, or if present before, were increased afterward. But casts and cells did not show any material numerical change. The writer concludes from this that the so-called ether nephritis is "largely a medical scarecrow"; for if it were ever to appear, he says, it would seem that pre-existing renal disease and actual operation on the kidney should favor its development. As to the present results: Two of the five are, for the practical purposes of business and occupation, well. Two have died, at intervals of four days and six months after the operation. One is not relieved.

*Journal of the American Medical Association, Aug.* 15, 1903.

**The Proper Perineal Prostatectomy Incision.**—Nicholas Senn points out that it is essential to success that the external incision shall expose the prostate to sight and touch freely as is consistent with safety, and shall provide for free drainage of the bladder and of the perineal wound, and adds that experience has taught him that neither the semilunar incision of Zuckerkandl nor the triangular incision of Kocher accomplishes these objects satisfactorily. The incision which the author advocates combines the median incision with two lateral ones representing in outline an inverted capital letter Y. The lateral incisions are carried from the lower angle of the median incision to a point half way between the anal margin and the tuberosity of the ischium, cutting through about the same structures as are involved in lateral lithotomy. The wound is deepened by blunt dissection, hemorrhage being controlled as it arises, until the rectum has been detached sufficiently to allow of the membranous portion of the urethra and the lower segment of the prostate being distinctly seen and felt. The margins of the wound being well retracted, the membranous portion of the urethra is incised upon a grooved staff and the grooved director of Wheelhouse is inserted into the bladder. With this as a guide the left index-finger dilates the prostatic portion of the urethra and acts as a blunt hook for drawing the prostate downward and forward. The capsule of the gland is then incised transversely, and with the opposite index-finger the enucleation of the left lobe is commenced. He usually finds it better to remove only one lobe of the prostate at a time. He favors preliminary cystotomy, and invariably drains the bladder until the condition of the urine warrants the discontinuance of intravesical medication.

*The Medical News, August* 15, 1903.

**Prevention of Rabies.**—Follen Cabot discusses the best methods of preventing rabies, especially the treatment of wounds caused by the bite of a rabic dog. The extent of the wound, he says, has much less significance than its position and after-treatment. Bites on the face are the most serious, and other exposed parts, as the hands and arms, come next in point of gravity. As to the size of the wound, one no deeper than a pin scratch may be the cause of an infection. In cases of wounds about the face and exposed parts, the patient should be put under a general anæsthetic, if necessary, and the wound scrubbed out with a brush, first with green soap, then with bichloride of mercury 1 to 1,000. This should be done as if for an operation. After this, fuming nitric acid should be carefully applied by means of a pointed glass rod. The wound should then be dressed surgically. If no anæsthetic has been given, Cabot uses first cocaine after the scrubbing, then pure carbolic acid followed by fuming nitric acid. This must be done as early as possible, but it is of value even as late as two days. In the absence of nitric acid the actual cautery is the best substitute, but it is sometimes difficult to reach each small point with this agent. This treatment of the wound within twenty-four hours of its infliction, the writer believes, is of more value than the Pasteur method, but he says that the latter should not be neglected, as it is undoubtedly of great efficacy if begun early.

*New York Medical Journal, August* 15, 1903.

**The Significance of Jaundice as a Symptom in Disease of the Biliary Tract.**—John B. Deaver naturally treats of this subject more particularly from the surgical standpoint. His conclusions are: (1) Jaundice is absent in the majority of cases of gallstone disease simply because in most instances the stone is situated in the gall-bladder. (2) Jaundice following acute gastrointestinal symptoms points to a catarrhal condition of the ducts, and may be followed by suppurative cholangeitis, in which case there will be deep jaundice, enlargement and tenderness of the liver, fever, sweating and chills, with gastric and intestinal disturbances. (3) Jaundice following chronic gastrointestinal symptoms is usually dependent upon chronic pancreatitis with induration and enlargement of the head of the pancreas. Gallstones may or may not be present. In the author's experience there has been some enlargement of the head of the pancreas in nearly one-fourth of the cases of gallstones. Malignancy must, of course, be excluded. (4) Acute obstruction of the common duct by a stone furnishes characteristic and easily recognizable symptoms, while chronic impaction is followed by the intermittent type of jaundice without enlargement of the gall-bladder, or else by no jaundice whatever. (5) Enlargement of the portal glands situated along the course of the common duct sometimes causes jaundice and simulates gallstone obstruction.

**Phlegmasia Alba Dolens and Its Treatment.**—Herbert Marion Stowe says that all authors admit the main factor in the etiology to be thrombophlebitis, but the unknown determining cause is probably, as Tilbury Fox has suggested, an obstructive lymphangeitis. Phlegmasia dolens in the puerperal woman may arise from three causes: (1) Thrombophlebitis of the main efferent vessels of an extremity, having its origin in the placental sinuses; (2) thrombophlebitis inflicted upon the pelvic veins and lymphatics, especially in difficult and tedious labors; (3) infection from the entrance into the blood of bacteria or their toxins. The condition of the blood must also be taken into account. Normally, thrombi fill the uterine sinuses only as far as the external coat, but if the uterus is relaxed, and its sinuses imperfectly closed by muscular contraction, a rapid absorption following a sudden loss of blood is apt to carry beyond the border line any clots or pieces of decidua that may lie detached in the uterus, and then it is but a step more for the thrombus to extend to the pampiniform plexus and through the internal iliac to the common iliac vein, and then attack the return circulation of the entire extremity. In the parturient canal one finds a large wound and absorbing surface and a morbid fluid ready to be absorbed. If, then, this fluid is infective it is to be expected that there will be phlebitis not only at the points predisposed, but in other parts of the body. The subject of treatment is embraced in the one word, prophylaxis. By preventing impoverishment of the blood during pregnancy, making use of such measures as will insure a proper coagulability of the blood, the avoidance of postpartum hemorrhage, of infection and the protection of the perineum from laceration, the occurrence of phlegmasia dolens will be reduced to a minimum. When it occurs, the limb should be placed on a slight incline in bed, and swathed in hot gauze compresses. After the first week gentle massage is indicated, but probably the best treatment for the subacute stage consists in subjecting the limb for an hour daily to a dry heat of 400°F.

*American Medicine, August* 15, 1903.

**Etiology of Enteroptosis.**—Thomas R. Brown discusses the various theories held regarding the causation of enteroptosis, grouping them as follows: (1) The condition is congenital and is due to an inherent weakness of the tissues which support the abdominal viscera; such factors as clothing, trauma, disease, etc., are not the primary causes of the condition, but simply contributory causes, which bring out and accentuate the inherited tendency. (2) The condition is due to the pressure of clothing, trauma, weakness of abdominal walls, various diseases associated with marked loss of strength or weight, various spinal and thoracic diseases, pregnancy, and parturition, abdominal tumors of various kinds; in other words, a number of conditions, each of which, however, has as its results the weakening of the various visceral supports, due in some cases to pressure, in other cases to adhesions, in other cases to trauma, and in still other cases to a marked diminution in the supporting power of the abdominal walls. (3) Each of the foregoing may be the primary causes of the condition; in other words, there is both an acquired and a congenital form of enteroptosis. A careful consideration of the various theories evolved and of the cases of enteroptosis described in the literature and met in his own experience inclines the writer to take this third view. As to the exact way in which the ptosis is produced there are a number of possibilities, but the suggestions of Keith, that the diaphragm is the most important factor in the production of this condition, he says, should receive most careful consideration.

*The Lancet, August* 8, 1903.

**Can the Respirable Products of Human Waste Hinder Development and Lower Vitality?**—John Hartley earnestly discusses this topic, which, he says, "must from its very nature be either utterly fatuous or of truly vital im-

portance." He takes the latter view of it, and endeavors to show by familiar scenes and experiences in the crowded out-patients departments of hospitals that the sallow, flabby, easily fatigued coming there are in this poor physical state because they have habitually inhaled an atmosphere made foul by the volatile products of human waste. These people are said to be as well fed on the average as the country poor. His argument is largely based on the ease and directness of absorption of such products as compared with the route by the stomach. Attention is directed to the well-known fact that muscular fatigue is coincident with the accumulation of muscle waste, and it is pertinently suggested that other people's waste is quite as capable of causing fatigue as our own. The author closes his interesting article with the thought that perhaps, after all, many of the ills usually ascribed to the high pressure of modern civilization may be more justly attributed to the effects of the toxins given off by our crowded population.

**A Case of Septicæmia.**—F. J. Strong Heaney reports this case because of the interesting group of symptoms and the fact that the favorable outcome seemed to be fairly attributable to the use of antistreptococcic serum. This is the more remarkable because, although the bacteriological examinations were far from complete and satisfactory, they failed to show the presence of streptococci, though staphylococci and diplococci were found in the blood. The patient was a woman of twenty-one, who a fortnight previously had injured the great toe, and, as a result, had developed a septicæmic process. On coming under observation, a little turbid fluid and a drop of pus were evacuated from under the injured nail, and a mass of inflamed, but not suppurating, glands was found in the groin. There were groups of herpetic vesicles on the forehead, upper and lower lips, and on both the lower eyelids; on the trunk and lower limbs were numerous pustules, while on the legs from the knees downward were lesions presenting the typical appearance of erythema nodosum. There was marked constitutional disturbance, but examination of the heart, lungs, and abdomen was negative. A short course of medication with the salicylates failed to give any relief. On the fourth day a scarlatiniform eruption appeared on the dorsum of each foot and on the legs, but subsequently became purulent. At this time a cardiac murmur was audible, which altered its character from time to time, evidently being dependent upon an acute endocarditis. On the evening of the fourth day 10 c.c. of antistreptococcic serum were injected, and this was repeated twice daily for three days, and once a day for two days more, when the temperature no longer rose. The cardiac murmur permanently disappeared two weeks later.

**Ichthyol in the Treatment of Pulmonary Disease.**—James Burnet, who has made an extensive study of the therapeutic properties of ichthyol, describes its action in thirteen cases of pulmonary tuberculosis of the ordinary slowly progressive type. Of this number, eleven were distinctly improved, the two failures occurring in very advanced cases. As a rule, the cough was markedly improved by the end of the first month, and this improvement was more noticeable after the second month, and was then associated with an improvement in and a diminution of the expectoration. No night sweats were seen after the fourth month, and in seven of the patients it ceased at the end of the third month. After the fourth month there was only slight cough with a scanty morning expectoration. By the end of the sixth month every one had gained in weight from three to seven pounds. Benefit from ichthyol was also noticed in a few cases of bronchiectasis, chronic bronchitis, and chronic pulmonary fibrosis of stone masons. The ichthyol was invariably given in capsules containing four grains of the remedy. At first two capsules were given four times a day, and this was gradually increased up to five capsules four times a day. Very few showed any repugnance to the medicine, and gastric irritation was never produced; indeed, the ichthyol was rather soothing than otherwise to the stomach. The author asserts that there is no evidence in support of the belief that the beneficial action of ichthyol in pulmonary tuberculosis is due to antiseptic properties. It unquestionably favorably modifies nutrition, but not so much because of its contained sulphur as from the influence of the sum total of the elements composing this definite chemical compound. Ichthyol is slightly antispasmodic, and in this way it relieves cough, but its chief action is as a vasoconstrictor, and by virtue of this property it prevents further exudation and inflammation.

*British Medical Journal, August* 8, 1903.

**Treatment of Brachial Neuralgia.**—Charles J. Whitby reports a case of brachial neuralgia following a fall from a horse. The injury was on the right side, and wasting of the biceps in particular was very marked. There was also tingling pain in the course of the ulnar nerve. Electrical stimulation very soon restored the wasted muscles to their normal bulk and enabled the patient to move the arm with comparative ease. The pain proved more lasting, shifting from point to point, but was always relieved for a time after treatment. The larger (negative) electrode was applied near the upper dorsal vertebræ, while the smaller (positive) one was moved over the painful parts of the shoulder and arm. The current was of just sufficient strength to cause a slight deflection (one or two milliamperes) of the needle of a galvanometer, while passing through the limb.

**Instances of Apparent Infection of Rheumatism.**—R. T. Turner reports three cases of this nature. One of his patients asked his brother, who was recovering from an attack of acute rheumatism contracted and treated in a neighboring town, to come and stay with him for some weeks. About a week after the arrival of his brother the host began to feel ill, had slight tonsillitis, followed by an affection of his legs, which appeared to be erythema nodosum, and a few days later developed a typical attack of acute rheumatism, which ran an ordinary course. I may say that the brother when he came down here had still remaining excessive perspiration and some stiffness of the joints, and presumably still had some of the rheumatic poison in his system. In a second case the writer was called to see a patient (aged twenty-two) in a village a few miles away, and found him to be suffering from acute typical rheumatism. He also found at the same time that the patient's sister was in bed with pains in her joints, and on examination he noted that she had marked rheumatic swelling of both ankles and one knee, and a temperature of 102.5° F. The brother is a railway porter, and lives in a small town. A fortnight before coming under observation he was attacked with acute rheumatism, and sent for his sister to nurse him. Exactly a week after her arrival she began to feel ill, had slight sore throat, and two days later had pain in her ankles. The third case was that of a young man aged nineteen living in lodgings, who was suffering from a very marked attack of acute rheumatism. His aunt, who lived in London, came down to help to nurse him. Three days after her arrival she complained of her legs causing her pain, and she soon developed an ordinary attack of acute rheumatism.

[*Münchener medicinische*] *Wochenschrift. July* 28, 1903.

**A New Operation for Old Ununited Fractures of the Patella.**—A. Schanz's operation consists in a transplantation of the insertion of the sartorius. This muscle is removed from its normal course in its lower third and brought anteriorly until it passes directly over the anterior surface of the patella and is reinserted upon the anterior border of the tibia. As this muscle passes over the patella the fractured edges of the latter are brought together and made fast to it. In this manner widely separated segments of the patella may be brought together, and in addition the quadriceps is made to exert its action and thus prevented from atrophy. The joint does not need to be opened during the operation.

**Spontaneous Recovery from an Invaginated Ileum Following Evacuation per Rectum of the Intussusepted Gut.**—Herm. Schridde had a patient, sixty years of age, a female, who was suddenly seized with a violent attack of abdominal colic. A diagnosis of intestinal occlusion was made. Seventeen days thereafter there was evacuated per rectum a section of the ileum 32 cm. long. Following this the symptoms rapidly subsided, and after eight days complete recovery had taken place. Four and a half months following death from a pulmonary trouble occurred. At the autopsy there was found a circular scar completely surrounding the ileum 36½ cm. from the ileocæcal value. The causation of these acute cases of invagination of the ileum is not entirely clear. Doubtless in many cases the cause is to be sought in the presence of a large foreign body. A lax mesentery is certainly an accelerating factor.

**Albuminuria in Aortic Insufficiency.**—V. Leuoe reports a case to show that albuminuria may occur in connection with aortic insufficiency not only in the stage of non-compensation and as a result of a venous congestion of the kidneys resulting therefrom, but at a time when compensation is perfect and no venous congestion is present. Such an albuminuria is peculiar to aortic insufficiency as opposed to other cardiac lesions. In old age such an albuminuria may be due to a general atheroma, but in young individuals, such as the case here reported, the cause is to be sought in the increased blood-pressure and marked variations of pressure which are present in aortic insufficiency in contradistinction to other cardiac lesions. In this manner there are pro-

duced changes in the walls of the blood vessels of the kidney and an increase in the interstitial tissue of the same. Thus there gradually arises an arterial induration of this organ. The epithelium of the glomeruli degenerates and albuminuria appears. Later the same occurs in the tubular epithelium and casts appear in the urine.

**Pathogenesis of Acute Psychoses.**—Hans Berger has endeavored to ascertain whether or not in the blood of acute psychotics toxins are present which stand in etiological relation to the disease. In a series of experiments he inoculated subcutaneously into himself the blood of several patients, and in one instance the spinal fluid. The latter experiment was entirely negative, as were also three of the five blood experiments. The remaining two, however, were apparently positive. In both of these the blood was taken from a fully developed case of dementia præcox. In one case 5 c.c. of blood was used and in the other three. Symptoms appeared in from one-quarter to three-quarters of an hour after the inoculations and consisted of dizziness, headache, and marked restlessness. In the first instance all symptoms vanished within twenty-four hours, but in the other recovery was prolonged for eight days. From this it is apparent that the presence of toxins in the blood of acute psychotics is at least highly probable. Animal experimentation was next instituted in order to demonstrate the development of cytotoxins under definite conditions. The most satisfactory results were obtained by the subcutaneous inoculation of goats with the brain substance of dogs. In this manner there is obtained a goat serum which is cytotoxic for dogs upon subcutaneous injection. Dogs thus treated regularly show an inflammation and degeneration of the brain tissue. The goat serum, however, becomes inactive if mixed with brain substance previous to inoculation. This shows, without doubt, that the cytotoxin is specific for the cerebral cells and becomes permanently united to them. The series of experiments is still underway, and a large amount of work is necessary before positive conclusions can be drawn.

*Deutsche medicinische Wochenschrift, July 23, 1903.*

**Diseases of the Vascular System Which Are Probably Nervous in Origin.**—T. L. v. Criegern reports a case which is of uncertain etiology, although it is extremely probable that the underlying cause was a general contraction of the vasomotor system due to effects upon the nervous system of a previous syphilitic infection. The clinical history may be divided into three groups of symptoms. The first group comprised hemorrhages—menorrhagia, epistaxis, and hemorrhagic nephritis. In the second group was the symptom-complex known as Raynaud's disease. Here the cyanotic and anæsthesic condition of the fingers was entirely characteristic of that affection. The third group was limited to petechiæ of the skin of the lower portion of the abdomen and back. These were late in appearance and very similar to that eruption known as morbus maculosus. There can be but little doubt that in this case the same etiological factor underlay the diversified clinical picture, and this consisted of a general contraction of the vasomotor system—in other words, a generalization of Raynaud's disease

**Bacteriological Diagnosis of Cholera and the Specificity of Koch's Comma Bacillus.**—W. Kolle and E. Gotschlich submit a review of the work done under their supervision during the recent epidemic in Egypt, by H. Hetsch, O. Lentz, and R. Otto. An absolute bacteriological diagnosis can be made in sixteen hours. To this end a portion of the specimen to be tested is cultivated according to Koch's method in pepton-water for eight hours. Plates are then made from this culture in agar and incubated for eight hours. From these plates the suspected colonies are then "fished," and the organisms thus obtained tested for agglutination against known cholera serum. By this method certain vibrio are frequently isolated which are very similar to Koch's organism in morphology and cultural characteristics, but which fail to agglutinate when tested with the cholera serum. Such organisms were isolated from the stools of sixteen of twenty-three clinical cases of cholera. In two of the sixteen Koch's vibrio was also isolated. In fifty-seven the latter alone was obtained. It is thus seen that in addition to developing a new and absolute bacteriological method of diagnosis the result of the work has confirmed the specificity of Koch's organism to this disease.

**Diabetes and Skin Diseases.**—Edmund Saalfeld reviews this subject and points out the value of the persistent appearance of various cutaneous diseases in the early diagnosis of diabetes mellitus. It should be particularly emphasized that in all cases of refractory cutaneous affections the urine should be carefully and frequently examined for the presence of sugar. In their relation to diabetes skin diseases may be divided into two classes: (1) those which occur only in connection with this disease and are therefore peculiar to it; (2) those which appear only as accidental accompaniments. The first class is very limited and includes xanthoma diabeticum, diabéte broncé, gangrena diabetica, gangrena diabetica bullosa serpiginosa, and dermatitis diabetica papilomatosa. The second class is very extensive. Here we have as the most prominent furunculosis, carbunculosis, eczema, the various forms of acne, paronychia, pruritus, urticaria, etc. The cutaneous symptoms of syphilis must also not escape notice in this connection, for it is well known that this disease is frequently an etiological factor in diabetes. Extensive experience has shown that the local treatment of cutaneous diseases appearing in unison with diabetes is futile, and that in order to obtain satisfactory results in any measure attention must be directed to the constitutional condition.

*French and Italian Journals*

**The Action of Red Light in Smallpox.**—Ch. Mongour reports a case in which red light appears to have hastened the desiccation of the confluent pustules on the face; on the rest of the body it did not prevent the transformation of the vesicles into pustules, but it probably prevented cicatrization. The author says that the treatment was not carried on with sufficient system to allow of definite conclusions, but suggests that further experimentation be made in this line.—*Gazette Hebdomadaire des Sciences Médicales*, July 26, 1903.

**The Action of Olive Oil on Microbes.**—An editorial calls attention to the value of olive oil when used in operations which leave freshened surfaces, when there is an effusion of lymph, or when there is irritation or inflammation of the pelvic or abdominal organs or the peritoneum. The results obtained have been excellent. Irritation and inflammation are allayed and adhesions are prevented. As to the action on microbes, it is found that microorganisms can and do live in oil, but perhaps do not act with their usual virulence. They multiply, but very slowly. The author says that although bacteriology does not give absolutely satisfactory data, clinical results have been so excellent that he has no choice except to persevere in the use of this agent.—*La Revue Médicale du Canada*, July 29, 1903.

**The Kidneys in Laennec's Cirrhosis of the Liver.**—G. Milian and Marcel Bassuet have found that out of eighty-nine cases of this affection albuminuria was found in only three. At autopsy a macroscopical examination showed the kidneys to be absolutely normal in nineteen cases; apparently normal but more or less hypertrophied in fifty-three cases. In seventeen cases only were there real lesions, five of sclerosis; four of congestion, three of atrophy, one of atrophy of one kidney and hypertrophy of the other, and one with a few cicatrices. Such microscopical examinations as were made confirmed the macroscopical findings.—*Bulletins et Mémoires de la Société Anatomique*, April, 1903.

**Pleural Eosinophilia.**—F. Barjon and A. Cade have found, by experimentation, that cytologically, two forms of eosinophilia are found in pleural effusions. The first is *relative* and in it the eosinophiles rarely go beyond 2—5 per cent. It is found most frequently in pleurisy which is proved by its clinical course, by inoculation, serum-diagnosis and cytology to be tuberculous. The other, which may be called *true eosinophilia*, varies from 10 to 74 per cent., and is found in pleurisies which are usually acute, with slight effusion, little tendency to reproduction, and not causing tuberculosis in a guinea-pig. Some cases are tuberculous and some are not, so that this form of eosinophilia cannot be absolute as to diagnosis; it does, however, indicate a light form of tuberculosis when there is any, and is therefore of value as to prognosis.—*Archives Générales de Médecine*, July 28, 1903.

**The Nerve Cell in Meningitis.**—Ezio Luisada believes that anatomico-pathologically no clear distinction can be made between meningitis and meningism, there being merely a difference in the localization of the morbid agent. From his researches he has found that the nerve cell is always affected in the various forms of meningitis. The lesion depends on the quality of the morbid agent, and the intensity and duration of its action as well as on the changes in the nutritive surroundings of the cell from inflammation of the tissues and alterations of the cell prolongations, and the amount of resistance possessed by the cell. The resistance offered by the new cell does not appear to depend upon its situation in relation to the distribution of the meningeal exudate. Although it is not yet possible to judge of the morbid cause of the disease from the species of cell lesion, we can often judge of the gravity of the infection, and sometimes of its duration.—*Rivista di Clinica Pediatrica*, July, 1903.

# Book Reviews.

HYGIENE AND PUBLIC HEALTH. By LOUIS PARKES, M.D., D.P.H. London Univ., and HENRY KENWOOD, M.B., D.P.H., F.C.S. Second Edition. Philadelphia: P. Blakiston's Son & Co., 1902.

THE authorship is in itself a guarantee that this treatise is comprehensive and scientific. and the need for a second edition within a year proves that it has been appreciated. The older and familiar book of Dr. Parkes has been practically recast, and the whole subject brought up to date. On disputed points the opinions expressed are critical, though conservative. For example, while admitting that bacteriological experiments point to the harmlessness of sewer air, the comment is made that this is not entirely in accord with practice. We could wish, however, that they had been somewhat more outspoken regarding the supposed relation of sewer air to puerperal fever, and had brought forward the "very considerable body of evidence" which they say is now being accumulated "to show that puerperal fever may be produced by sewer or drain emanations finding their way into the chamber of the lying-in woman." A careful perusal of the articles on house-plumbing, ventilation, the injurious effects of dusty occupations and industrial poisonings, and the method of investigating disease outbreaks will well repay any physician.

SURGICAL EMERGENCIES: THE SURGERY OF THE HEAD. By BAYARD HOLMES, B.S., M.D. New York: D. Appleton & Company, 1903.

THE volume before us is one of a series that is to deal with the commonly encountered surgical diseases. Commonness, and frequency of occurrence do not, however, class a surgical affection into the category of those that are by most of us considered as emergencies. The title of the *series* is misleading.

The author intends these books especially for the use of the general practitioner, and in the volume upon the surgery of the head he has very properly devoted most attention to pathology, symptomatology, diagnosis, and indications for treatment. The descriptions of diseases are much strengthened by reports of cases occurring in the author's own practice, or drawn from literature. Especially clear and accurate are the chapters upon cerebral compression, brain abscess, and sigmoid sinus thrombosis; their close study should be of much value to the general physician.

Though the author has not entered very much into the purely operative aspects of surgical diseases of the head, it is somewhat surprising that he makes no mention of the great value of paraffin injections for the improvement of nasal and other facial deformities.

The book is well illustrated and nicely printed. A short résumé of the literature is appended to each chapter.

DE LA GLYCÉRINE, PHYSIOLOGIE, THÉRAPEUTIQUE, PHARMACOLOGIE. Par A. CATILLON, President Honoraire de la Société des Pharmaciens de 1re Classe de Paris, Ex-Interne des Hôpitaux de Paris, Membre de la Société de Thérapeutique. Paris: C. Naud, 1903.

THIS monograph, treating upon the physiological, therapeutical, and pharmacological qualities of glycerin, is a welcome addition to our literature. There is not much original work incorporated into the little volume of 191 pages. Its value depends upon clearness of diction and the exhaustive and yet condensed treatment of the subject. The second part of the book, in which the physiological properties of glycerin are considered, is especially interesting

DISEASES OF THE HEART AND ARTERIAL SYSTEM. Designed to be a Practical Presentation of the Subject for the Use of Students and Practitioners of Medicine. By ROBERT H. BABCOCK, A.M., M.D. Professor of Clinical Medicine and Diseases of the Chest, College of Physicians and Surgeons (Medical Department of the Illinois State University), Chicago. New York and London: D. Appleton & Company, 1903.

THE volume before us bids fair to become one of the most popular works on circulatory diseases, notwithstanding the many rivals that have appeared. The author seems to recognize the difficulties which beset the student and practitioner, and proceeds to clear away these difficulties with the practised hand of the experienced teacher. From beginning to end the work is eminently practical and will be found well adapted to clinical workers. The writer makes no claims to originality, but for this very reason there is an absence of personal hobbies and an extremely fair exposition of the subject. Sufficient attention has been paid to the anatomy and physiology for all practical purposes, while the main part of the book is given up to diagnosis and treatment. Too much praise cannot be paid to these portions, for they are extremely helpful, instructive, and sound. The problems of exercise, occupation, habits, marriage, clothing, baths, food, illnesses, rest, diet, climate, the Schott-Nauheim treatment, etc., are discussed broadly and clearly. The bulk of the work is apportioned to the diseases of the endocardium and of the myocardium, at the same time sufficient space is afforded to pericardial, neurotic, and arterial abnormalities.

A short appendix describes some of the mechanical devices used in determining cardiac disease, such as the *x*-ray, the sphygmograph and Gaertner's tonometer. The incorporation of plates showing pathological conditions, diagrams explaining the various murmurs, and the different resistant movements of importance has served to make an exceptionally clear text very readily understood.

ESSAYS ON CLINICAL MEDICINE. Being Reprints of Papers Published at Various Times in the *American Journal of the Medical Sciences*. By BEVERLY ROBINSON, A.M., M.D. (Paris). Clinical Professor of Medicine at the University and Bellevue Hospital Medical College; Attending Physician to St. Luke's Hospital; Consulting Physician to the City (Charity) Hospital, New York. Philadelphia: William J. Dornan, 1903.

THE essays before us express the ideas of the author on many different subjects. Among them may be noted articles on uræmia, heart disease, cough, angina pectoris, cirrhosis of the liver, and tuberculous pericarditis. Drawing from a large experience in both private and hospital practice, the writer treats of subjects that are of every-day interest in a way that will appeal to the general practitioner. The problems which we all must meet seem to have been especially considered, and particularly those which have not received proper attention from the text-books. To make the points which the author advances more incisive, clinical histories and autopsy records have been added. Altogether the collection makes most interesting and instructive reading.

THÉRAPEUTIQUE CLINIQUE. Les Médicaments, par le Dr. ALFRED MARTINET, Ancien Interne des Hôpitaux de Paris. Paris: C. Naud, 1903.

IN this book of 284 pages a number of medicaments have found a rather novel but seemingly rational consideration. Particular stress has been laid upon the points when, why, and how a certain drug should be administered. Twelve remedies: arsenic, bromides, digitalis, ergotine, iron, iodides, mercury, quinine, phosphorous, opium, salicylates, and antidiphtheritic serum, and one class of medicaments;, the purgatives, are dwelled upon. The little work abounds in practical hints, the subject-matter is arranged in a logical manner, the language is simple and even readily understood by one who is not *au fait* in the French tongue.

A LABORATORY TEXTBOOK OF EMBRYOLOGY. By CHARLES SEDGWICK MINOT, LL.D., D.Sc., Professor of Histology and Human Embryology in the Harvard Medical School. With 218 illustrations. Philadelphia: P. Blakiston's Son & Co., 1903.

THE author has prepared this work for the use of students taking a practical laboratory course in embryology. He begins with a chapter on general conceptions, such as the vertebrate type of structure and its principal modifications, the relations of surface to mass, the law of unequal growth, the theory of heredity, etc. This is followed by chapters on the early development of mammals, the human embryo, study of pig embryos, of young chick embryos, the blastodermic vesicle, and segmentation of the ovum, and the uterus and fetal appendages in man. The last chapter deals with the methods which may be used advantageously in these embryological studies.

The student is expected to use the book in conjunction with specimens prepared for microscopical examination, and to verify the statements by actual observation. He will find descriptions of the structure of embryos at various stages of development, with some indication of the intermediate processes of differentiation and growth. The development of the human embryo is divided into thirteen stages up to the completion of the second month, and thereafter, by months.

The descriptions are clear, and well illustrated by the cuts, many of which are very beautifully executed.

A MANUAL OF MEDICAL JURISPRUDENCE, INSANITY, AND TOXICOLOGY. By HENRY C. CHAPMAN, M.D., etc. Third Edition, thoroughly revised. With 64 Illustrations and 4 Plates in Colors. Philadelphia, New York, London: W. B. Saunders & Co., 1903.

THE demand for Dr. Chapman's little book has led to the preparation of a third edition, although it contains little that is new. The chapter upon the investigation of blood is perhaps the best part of the book, but it is to be regretted that the modern transfusion tests are not presented. The manual is essentially practical, and is a useful guide for the general practitioner, besides possessing literary merit which makes it readable and interesting.

STUDIES IN THE PSYCHOLOGY OF SEX, Analysis of the Sexual Impulse, Love and Pain, the Sexual Impulse in Women. By Havelock Ellis. Philadelphia: F. A. Davis Co., 1903.

THIS volume is one of a series on the general subject of Psychology of Sex and deals with the analysis of the sexual impulse in man and animals, especially in its relations to pain and pleasure as incitive elements, and concludes with a discussion of the sexual impulse in women. The treatment of the different topics is dignifiedly scientific and singularly free from many of the objectionable features that frequently characterize works on similar subjects. The author has taken great pains in collecting his facts, and his analysis of their significance appeals to the logical sense of the reader. The study of the sexual impulse is, necessarily, that of a very complicated process, but the author quite successfully simplifies it by disposing of its separate component divisions in turn. The chapter is full of most interesting and instructive details, and affords the reader the broadest possible view of the universality of the sexual function and its different modes of manifestation in all the varied divisions of the animal kingdom.

The author believes that the chief key to the solution of the relationship between love and pain is to be found in animal courtship, the marriage by capture, and also in like exhibitions of brute force on the willing and responsively submissive female. The extremes of such conditions are duly detailed as typical instances of sadism and masochism. The accounts of the sexual instinct in savages are given in much detail, as are those of the instinct in the civilized female. The personal experiences of many voluntary correspondents detailing their various neuropathic tendencies also form a feature of the work.

LES PHÉNOMÈNES DE SUGGESTION ET D'AUTO-SUGGESTION. Par L. LEFÈVRE. Brussels: Henri Lamertin, 1903.

A CREDITABLE attempt has been made by this author to place the study of suggestion upon a material basis, which is most welcome, for the tendency of those who have written during the past few years is to write entirely from a purely psychological standpoint. The first part of the book is devoted to the psycho-physiological consideration of the subject, the cerebral mechanism of suggestion being illustrated by ingenious diagrams, which are, in many ways, better than speculative word painting, no matter how fascinating the latter may be. The reader will find the medicolegal chapter most attractive, for the relations of suggestion to crime are given their proper value. The bringing of charges of immoral assault as a result of autosuggestion by young girls are described, and a case is referred to. Heretofore it has been the tendency of criminologists and others to regard all these cases as "hysterical," and to take for granted the vicious motives of the subject. Blackmail is the inevitable conclusion. Dr. Lefèvre very clearly shows that the charge may be in every way an irresponsible one, in which conclusion the reviewer concurs.

ANATOMY OF THE BRAIN AND SPINAL CORD, with Especial Reference to the Grouping and Chaining of Neurones into Conductive Paths. By HARRIS E. SANTIE, M.D., Ph.D.; Chicago: E. H. Colegrove, 1903.

THE third edition of this useful work differs but little from those that have preceded it, except that extensive addenda have been added, bringing the book up to date. Its value depends upon its unusual lucidity, directness, and freedom from much of that terminal affectation so characteristic of the neurological literature of to-day. The terms used are those best known, or should be, to students of this branch of anatomy, and their Latin or Greek equivalents are placed as foot-notes. While much that the author says has been stated by others in more pretentious books, no English or American writer has made the subject of cerebrospinal anatomy more clear or readable, for he pictures neurone relations and typographical association and conduction in a way to be easily recalled and used. While the little book is unpretending, it contains most of the accepted views of advanced neurologists. An attractive feature is an excellent and copious index.

THE INTERNATIONAL MEDICAL ANNUAL: A Year Book of Treatment and Practitioner's Index. Twenty-first Year. New York and Chicago: E. B. Treat & Co., 1903.

THE first thing one notes on picking up this volume is that it outweighs its predecessors. In man a gain in weight is oft looked upon as an evidence of gain in health. Can we always argue that the heaviest books contain the most weighty matter?

The editors claim never to have posed as censors of medical opinion, and, in the twenty-one years of continued growth of this annual, have striven to present the conclusions of medical writers; condensed and elucidated, but not weighed nor appraised. We will, in turn, strive to appraise without actually weighing.

The work, on careful inspection, is found to be of the usual high order of compilation, and the list of contributors of original matter contains many well-known names.

There are many illustrations, and those bearing upon the newer methods of light-treatment seem to be in the majority.

We can only congratulate the editors on the Annual's attaining its majority, and trust it may continue to improve without putting on more avoirdupois.

ÜBER DIE WIRKUNG DER BORSÄURE UND DES BORAX. (EIN ZWEITES GUTACHTEN.) Von Dr. OSCAR LIEBREICH, o. ö. Professor der Universität Berlin und Geheimer Medicinalrath. Berlin: August Hirschwald, 1903.

LIEBREICH gives a most instructive résumé of the effects of boric acid and borax in their rôle of preservatives and therapeutic agents. In order to investigate the changes caused in the organism by these substances, he administers them to animals, which he later dissects. There are a number of colored plates appended, which represent the differences between the normal kidney and that organ after the injection of these substances. There are various clinical histories given of patients suffering from a variety of affections. These show the results of treatment by boric acid and borax. The monograph is full of interesting information.

MATERIA MEDICA FOR NURSES. By JOHN E. GROPP, Ph.G., Apothecary in the Rhode Island Hospital, Professor of Materia Medica, Botany, and Pharmacognosy in the Rhode Island College of Pharmacy. Second edition revised and rewritten. Philadelphia: P. Blakiston's Son & Co., 1903.

THE original abridged form of statement has been maintained in rewriting much of this guide for nurses. It is a compilation with arrangement of subjects to meet the requirements of those for whom it is intended. There has been some changes from the first edition, which improve the work.

DISEASES OF THE STOMACH. By FRANZ RIEGEL, Professor of Clinical Medicine in the University of Giessen. Edited with additions by CHARLES G. STOCKTON, M.D., Professor of Medicine in the University of Buffalo. Authorized Translation from the German, under the editorial supervision of ALFRED STENGEL, M.D., Professor of Clinical Medicine in the University of Pennsylvania. Nothnagel's Encyclopedia of Practical Medicine. American edition. Philadelphia, New York, London: W. B. Saunders & Co., 1903.

THIS volume of Nothnagel's Encyclopedia, dealing only with stomach diseases, has already made a reputation in Germany, and to praise it would be superfluous. One could not wish for a more complete exposition of the subject, nor for a less prejudiced work. The author throughout looks at his subject from the standpoint of the judge and not that of an advocate; for instance, acknowledging that the numerous quantitative examinations of free and combined hydrochloric acid have not been followed by the brilliant results which had been expected. Still, on the other hand, he claims the laurels won by those in his specialty, and truly proves that many formerly hopeless cases are now cured by the present methods.

The pathology, etiology, symptoms, prognosis, diagnosis, and treatment are all thoroughly considered, and in the most practical manner. The author aims to teach the reader, and we think succeeds. The relative values of the various chemical tests are carefully weighed and the benefit of the writer's experience added. The editor's part has been well performed, he having added such material as he deemed necessary, and assuming full responsibility by bracketing each alteration. Among these changes may be mentioned a few remarks on the subjects of diet in hyperacidity, digestion leucocytosis, benign tumors, operative procedures, congenital stenosis, etc.

THE MANUAL TREATMENT OF THE DISEASES OF WOMEN. By GUSTAF NORSTRÖM, M.D., of the Faculty of Stockholm. New York and London: E. G. Stechert, 1903.

THE author treats his subject in a most enthusiastic manner and awakens interest in this method by his presentation of it. His first treatise, the first scientific work on this subject, was published in 1876. His experience in this line has extended over a period of more than thirty years. In the greater number of his patients, douches, pessaries, general treatment, cauterization, and curettage, had been employed. But none of these procedures was followed by lasting benefit. The condition of the patients was carefully noted at the beginning of the massage, which was the only treatment given. Enough of the patients have been seen for later examinations to speak well for this method, which is Brandt's proceeding modified. The descriptions of technique are plentifully interspersed with histories of cases.

### SECTION ON DISEASES OF CHILDREN.

*Tuesday, May 5—First Day.*

**Address of Chairman: "The Development and Care of Children."**—Dr. JOHN C. COOK of Chicago delivered this address. He said that while in the fœtus the heart represented 0.89 of the whole, in adult life it was only 0.52. The changes in the nervous system from birth to maturity furnished many examples of the difference between the child and the adult. The fibers of the spinal cord, the medulla oblongata, the corpora quadragemina and pons Varolii were, in early life, mainly somatic. It was our duty to guard and conserve every atom of energy during this period of budding life, realizing that they were bundles of possibilities unsolidified. The speaker then considered the child-labor question, and what had been done by the different States to protect children. Massachusetts was one of the first to move in this direction, and at the present time no child under thirteen was allowed to work. All States having labor laws took the age of the child as the basis, and the parents' affidavit was considered all-sufficient. Herein was the great defect. It was estimated that there were in the United States no less than 1,750,000 wage-earners under the age of fifteen years, and that the number had increased a hundred-fold in the past ten years. The State could better afford to support and educate a child than it could to support and discipline criminals among adults. It was not labor that made or marred character, but the environment during the developing period. It was within the province of the medical profession to see that children who must work be provided during the day with 250 cubic feet of air, and the night workers with 400 cubic feet, and that the entire air be changed every hour. The speaker recommended that each State have a commission of five members, at least two of whom should be physicians, and that this commission have jurisdiction over all matters of education and labor, this commission to be appointed by the Supreme Court judges of the State, and they, in turn, to appoint or nominate inspectors, so that the question of child labor should be forever removed from petty politics and vicious contract labor.

**Anatomical and Physiological Correspondence of Child and Adult.**—Dr. WILLIAM T. ECKLEY of Chicago read this paper. He said that the child possessed mental and physical qualities of heredity only, whereas the adult possessed the same qualities modified by the activity of mind and body. Continuous stimulation tended to result in exhaustion; hence, adult doses, in comparison with doses suitable for children, represented not increased vigor, but the wane of receptivity. Idiosyncrasy was the survival in the adult of the normal susceptibility of stimulation in the child. This brought up the questions as to whether the physician was justified in beginning treatment with adult doses of powerful drugs, and whether idiosyncrasies should not be respected.

**Is the Study of Pediatrics Worthy the Attention It Gets, and Does It Get the Attention It Deserves?**—Dr. C. F. WARNER of Fort Madison, Iowa, read a paper with this title. He said that in view of the fact that few places outside of cities afforded the pediatrician full scope for his specialty, it followed that all physicians and surgeons should give more study to pediatrics. Practice among children opened up a good field for the young physician, because it introduced him into practice, winning for him the affection and respect of the mothers, and later making him the friend and confidential adviser of the family. The importance of having a good practical knowledge of pediatrics was evident from the fact that one-half of general practice was among children and adolescents, and this emphasized the need for more thorough instruction in this subject at our medical schools.

Dr. W. F. BOGGESS of Louisville, Ky., said that, as a teacher, he endeavored to impress upon his students the most optimistic views regarding the diseases of childhood, because of that large unknown quantity, resistance and recuperative power. The most discouraging cases could often be brought back to health.

**Acute Suppurative Cervical Adenitis of Infancy.**—Dr. THOMAS S. SOUTHWORTH of New York City was the author of this paper. He said that this was an affection which was peculiar to infancy, and resulted from the absorption through the lymphatics from the nasopharynx. The variation of the antero-posterior position of the tumor appeared to be due to the fact that one or both of two glands, lying on different planes, might become affected. Usually only one of these glands was affected. Personally, he had found it almost as frequent anteriorly as posteriorly. The child's head was thrown to the opposite shoulder, and a prominent mass was visible. Usually there was a temperature of from 101° to 103° F. associated with malaise. The mass was usually more or less tender, and when resolution occurred, decreased in size more or less rapidly after a few days. If suppuration developed, the outline of the mass became less sharply defined, and pointing would be noted after about two weeks. The fact that tuberculous adenitis rarely occurred before the beginning of the fourth year, and that the progress was rather a matter of months than of days, should prevent one from diagnosticating that variety when acute suppurative cervical adenitis was present. It was well to wait until pointing occurred, so that the scarring might be reduced to a minimum. The general surgical rule to lay open freely any pus cavity not having free drainage, had a notable exception in the cases under consideration. A small opening was necessary, and in this should be inserted the smallest possible drainage tube. Packing with gauze or the use of drainage wicks he had long since abandoned, as under their use the healing process had not been so satisfactory or so rapid. The child should be placed in a bright light, and the physician should then seek very carefully for one of the delicate lines marking the natural folds of the skin. Having found this landmark, an incision should be made at this point, without anæsthesia, for a distance of about ¼ of an inch, and then the evacuation of the pus favored by very gentle pressure. With the aid of a grooved director the cavity was thoroughly emptied, and then a fenestrated rubber drainage tube, about $\frac{1}{16}$ of an inch in diameter, and 1¼ to 1½ inches in length, should be introduced on a probe or director to the deepest part of the cavity. On the second day the length of the tube could usually be reduced one-half; on the second or third day there was usually very little discharge, so that the tube could be removed, and thereafter healing would be rapid. The abortive treatment was worthy of trial. He had tried ichthyol ointment as well as iodine, without avail. When there was fever, tablets containing ¼ minim each of tincture of aconite and tincture of belladonna and $\frac{1}{16}$ minim of camphor, should be given every two hours or oftener, according to the age of the child. Chlorate of potash had almost a specific action in limiting the pharyngeal inflammations of childhood. One or two grains should be given at intervals of two or three hours, and for cleansing purposes, Dobell's solution, or one made with Seiler's tablets, should be used. This sloution should be poured through the nose with a teaspoon every three hours. The results from this line of treatment had been immediate and extremely gratifying. In children over one year of age in whom formerly pus formation occurred frequently, there had been no failure. In infants under one year old there had been four failures, and in each of these cases the temperature had persisted, reaching 102° or more each day. This abortive treatment of cervical adenitis of infancy was most promising, especially in children over one year old. The younger the child the greater the liability to suppuration.

Dr. A. C. COTTON of Chicago spoke earnestly in favor of the daily toilet of the nose in children, and stated that

in the families in which he had succeeded in installing this practice there had not been in the past five years one case of suppurative adenitis.

Dr. C. G. KERLEY of New York also favored the use of a small incision, but added that if a tube were inserted, this opening would be very apt to close within twenty-four hours, necessitating its reopening. He had seen a number of cases of tubercular adenitis in children under four years of age, so that too much stress must not be placed on this point in making the differential diagnosis. In acute adenitis there would be fever, rather rapid tumefaction, and a distinct localization of the process; in tubercular adenitis it was not uncommon to find the whole chain of glands down to the clavicle involved. He was a strong believer in the efficacy of chlorate of potash internally in the treatment of the nasopharynx, and he thought whatever value the old iron and chlorate of potash mixture possessed was to be attributed to the chlorate of potash. It was most important to guard against the use of force in cleansing the nose and pharynx, and, hence, the fluid should be either dropped in or used in an atomizer. He preferred the installation of oil or albolene, medicated or plain. In the abortive treatment he had secured good results from the application of a small ice-bag.

Dr. R. B. GILBERT of Louisville said that superficial cervical adenitis often developed in connection with eczema of the scalp or dental caries. He was not in favor of local applications except, perhaps, the ice-bag, and certainly warm applications and ointments should be avoided. When iodide of potassium was administered internally every three hours, in full doses for the age of the patient, it certainly favored absorption, and, in his opinion, was a valuable abortive treatment.

Dr. C. F. WAHRER thought a great deal of harm was done the middle ear by the pressure resulting from the evolution of gas in the use of peroxide of hydrogen for cleansing the nasopharynx.

Dr. JAMES G. MASTIN of Chicago was of the opinion that the internal use of chlorate of potash would limit the formation of pus in suppurative adenitis, and if used sufficiently early, might wholly prevent abscess formation. He preferred normal salt solution to oily preparations for cleansing the nasopharynx.

Dr. SOUTHWORTH, in closing, said that he had always used the chlorate of potash cautiously, and had seen nothing but benefit from it; but a medical friend had recently told him of a case of acute nephritis that had developed in a girl of thirteen years after partaking rather freely of chlorate of potash lozenges. In his experience, the cases that had been benefited by iodide of potassium were either those having a syphilitic taint or those characterized by persistent induration.

*Wednesday, May 6—Second Day,*

**The Pathology of Summer Diarrhœas of Children.**—Dr. G. W. BOOT of Evanston, Ill., was the author of this paper, which, in his absence, was read by the Secretary. The author stated that diarrhœas of indigestion were more common in summer than in winter, because improper feeding and food infection were more prone to occur in the summer. If improper feeding were persisted in, there would result gastritis or enteritis. The term "cholera infantum" was best applied to the fulminating cases of food poisoning. There was usually but little visible on post-mortem examination, further than some congestion of the intestinal mucosa and, perhaps, an increased quantity of mucus. All of the tissues of the body might show the result of the large abstraction of water from the system as a result of the frequent watery stools. This class of cases merged imperceptibly into the next class, in which diarrhœa was due chiefly to bacterial infection of the intestinal contents and intestinal walls. Typhoid fever was nearly related to this class of diseases. In children typhoid fever was apt to run a shorter and milder course than in adults, and was frequently unassociated with intestinal ulceration. Streptococcus infection appeared to be an occasional cause of diarrhœa in children, most of the cases reported being those in which the diarrhœa was a part of the general septicæmia. Streptococci were often present in small numbers when the infection was evidently due to some other cause. Of fifteen cases of infantile diarrhœa in children between the ages of six months and seven years, Escherich had seven fatal cases. The disease was evidently contagious, and Escherich believed that the cause was the colon bacillus. It was probable that a bacillus of the same group as the colon bacillus, although of a distinct species, was the specific cause of most summer diarrhœas. This germ was the bacillus of Shiga. Flexner had isolated it from a case of dysentery in Manila. That it was the cause of the summer diarrhœa in children had been shown most conclusively by the work done by G. Duval and Bassett, who had isolated this bacillus from forty-two cases of summer diarrhœa occurring in the infants of Baltimore. The Shiga bacillus resembled the bacillus typhosus in many respects. These bacilli appeared as short rods with rounded ends, and they usually occurred singly, although sometimes in pairs. The mucous stools gave almost a pure culture of this bacillus. In the more chronic cases there was a marked infiltration of the intestinal walls, so that they were stiffer than normal, while the lumen of the intestine was lessened. The paper closed with a minute description of the pathological anatomy.

**Every-day Problems in Infant Feeding.**—Dr. HENRY ENOS TULEY of Louisville read this paper. He insisted that while occasionally the mother's milk did not agree with her infant, this was so exceptional that it only served to emphasize the unwisdom of weaning an infant from the breast without the best of reason. Attention was called to the occurrence of what Holt called starvation or inanition fever, and it was advised that the temperature of the new-born infant should be taken for the first week or two. If the breast milk was not secreted promptly the feeding of the child would often cause a prompt suppression of the fever and an immediate improvement in its condition. The child would often have colic with greenish stools and curds, due to excess of proteid. This would frequently correct itself after the lying-in period was over and the mother was taking the usual amount of exercise and was on ordinary diet. Temporary relief was afforded by milking out and excluding the first milk from the breast, allowing the child to nurse only the middle portion. Of course, it was assumed that the child had not been nursed too often or given too much at each nursing. If prophylactic care of defective nipples were begun sufficiently early, many mothers would be able to nurse their infants, whereas without such attention this became impossible. Mothers who were tuberculous, or were suffering from serious puerperal infection, should not nurse their infants. Mastitis he did not consider a contraindication to nursing, as the abscess rarely connected with the mild ducts, and hence nursing was an aid rather than a detriment.

With regard to artificial feeding, the speaker said that condensed milk has much to recommend it to poor people, but its long continuance resulted in scurvy and rickets, and when a change was indicated it was difficult to effect this because the infant had become accustomed to the very sweet taste of the condensed milk. Modification of milk at the home or laboratory should enable the physician in most instances to secure a proper food for the artificially fed infants, but in some instances the physician's resources would be taxed to the utmost to find a food which could be readily digested and assimilated. In conclusion, the author said: "Eternal vigilance is the price of success; trust nothing to nature unaided."

**Infant Feeding.**—Dr. ALEXANDER MCALLISTER of Camden, N. J., presented this paper. He said that he felt reassured by the ever-increasing evidence of the greater esteem for breast feeding as compared with artificial feeding. The laity judged of an infant food by whether or not the child lived, and whether it grew fat, ignoring, as a rule, the important question of morbidity. At the present time the profession was turning from wholesale sterilization or pasteurization and giving earnest attention to the individualization of feeding by the appropriate modification of cow's milk.

**The Infant Digestive Disturbances.**—Dr. ALFRED C. COTTON of Chicago read this paper. He said that statistics showed that the greatest susceptibility to summer diarrhœa occurred between the ages of six and eighteen months. The early cases occurred during the milk feeding period, while the later cases occurred from the age of eighteen to twenty-six months. The well-known clinical picture of the acute variety was presented, and attention directed to the fact that it was the picture of acute poisoning of the gastrointestinal tract. The widely differing opinions on the frequency and severity of cholera infantum could be reconciled by the fact that there was no uniformity in the use of this term. His own opinion was that cholera infantum was an intense form of acute gastroenteritis or a dyspeptic diarrhœa plus some unknown intoxication. Clinically, the line could not be sharply drawn between some cases of dyspeptic diarrhœa and cholera infantum. The question was raised as to whether there was not a tendency to restrict the diagnosis of cholera infantum to the fatal cases. The diagnosis of diarrhœa due to acute indigestion seemed to meet all the requirements, pathological or therapeutic. The most common complication of diarrhœa in young infants was stomatitis, and it became serious as it interfered with the ingestion of food and increased the restlessness and discomfort. It was most often seen when the gastric disturbance was marked. The frequent occurrence of albuminuria had led some to attribute the convulsions to uræmia, but this conclusion was not confirmed by the post-mortem findings in the majority of cases. A prolonged attack of summer diarrhœa seldom left the infant without evidences of retarded development, and the attempt to adapt the hygiene of such an infant to its age rather than to its condition was a common error. The fatalities of summer diarrhœa were rarely seen among infants who were exclusively breast-fed. The diarrhœas of the exclusively breast-fed were well known to be usually tractable regardless of season by the application of the well-known principles of hygiene. When pronounced diarrhœal symptoms appeared in an infant at the breast it should lead at once to a searching inquiry as to whether the child might have had some additional food. The treatment of infant indigestion was so essentially dietetic that the use of drugs must be looked upon as only supplemental. So far as he knew, no one claimed that artificial feeding could ever equal, to say nothing of rivaling, breast feeding. Selected cases under the most favorable conditions showed a lessened mortality when scientifically fed artificially, but if only a small fraction of the energy expended in this important field of artificial feeding were bestowed upon the physiology of lactation he felt sure that the results would far exceed those obtained even by our modern methods or artificial feeding. He was satisfied that the solids in breast milk would be found diminished as the heated term approached, whereas the tendency in artificial feeding was to increase the solids as the age increased without taking cognizance of the season.

**Suggestions for Reducing the Prevalence of Summer Diarrhœa in Infants.**—Dr. J. ROSS SNYDER of Birmingham, Ala., presented this paper. He began with the dictum that summer diarrhœa was the result of bacterial invasion, and pointed out that the disease was not only curable but was preventable. Unfortunately many practitioners still believed that heat and humidity alone without the agency of bacteria were sufficient to produce the disease, and consequently a large percentage of the medical body had failed to coöperate with those who were endeavoring to carry out prophylaxis. But it must be admitted that there were many difficult problems connected with home management and hygiene which had to be overcome. The family physician could do much by individual education toward promulgating the dictum already mentioned. Even breast milk was often contaminated through the careless habits of the mother. Cow's milk was, of course, more apt to become contaminated, and yet it did not follow that bad milk necessarily came from a badly conducted dairy, but might be the result of improper care of the milk in the household. It was remarkable that well-educated physicians who were making conscientious efforts to modify milk according to the most approved methods to the needs of the individual infant, paid no attention whatever to the milk supply. Just here came in the good work of milk commissions. On such a commission there were usually four experts, viz.: (1) A veterinarian, (2) a physician, (3) a bacteriologist, and (4) a chemist. The good results of such labor could not be denied, but the benefits which should accrue had been greatly curtailed by a lack of support from the general profession. The tenements of the poor furnished the hot-bed for summer diarrhœa, and the best way of reaching this class of people and showing them how to live so as to avoid sickness was by the distribution in these tenements of simple information printed in several different languages. This campaign of education should be supplemented by visitations made by a corps of medical undergraduate and post-graduate students.

**Observations on Breast Feeding from an Obstetrician's Point of View, with Report of Cases.**—Dr. EFFA V. DAVIS of Chicago was the author of this paper. She said that the safe delivery of the fœtus was not all for which the obstetrician was responsible. After birth the very helplessness of the infant should appeal forcibly to the obstetrician. In the first place, the pulsations in the umbilical cord should be allowed to cease before ligation of the cord, in order to give the infant the benefit of all the blood due it. She had found this method contributed to the tranquillity of the infant, and usually such infants were found at the end of the first week not to have lost weight. She gave personal attention to the first application of the baby to the breast, and saw to it that on the first day the interval of nursing was six hours, on the second day, four hours, on the third day, three hours, and after that that the intervals were two hours. A most useful device for preventing turgidity and caking of the breasts was the application on the second day of a Canton flannel breast binder extending from the armpits to below the breasts, and pinned from below upward. Where the nurse could not be trusted to readjust this binder after each nursing, a hole should be cut for each nipple and the binder should be kept on. It was easy to say that children were colicky from an excess of proteids, but it was a different matter during the puerperium to modify the lacteal secretion properly. Where the mother was strongly averse to nursing her infant, it was often noticed that the lacteal secretion was not normally established. Here, firmness and moral suasion would often bring the mother to a proper frame of mind, and in this way the breast secretion would be improved. When it was suspected that the breast milk actually disagreed with the infant, this suspicion could be confirmed or disproved by a short trial of a substitute for the mother's milk. Several difficult illustrative cases were narrated. Five infants presented digestive disturbances in the first week of life, and it had been found exceedingly difficult to nourish these children properly owing to an idiosyncrasy. The mothers of these babies had been anxious to nurse their children, but it should be

remembered that in these exceptional cases it was often better to make use of artificial food rather than allow a child to gain a paltry ounce or two a month simply to keep up the breast feeding.

**Aphthæ and Herpes Contracted by Children Drinking Milk from Cows Suffering from Foot-and-mouth Disease.**—Dr. E. F. BRUSH of Mount Vernon, N. Y., read this paper. He said that the foot-and-mouth disease usually lasted in the cow from ten to twenty-one days, and at the worst the mortality was only from one to five per cent. The speaker said that he had made a personal investigation with the object of determining the existence of herpes and aphthæ in human beings. To that end, he had investigated the subject in Concord, Mass., where 327 cattle had been recently killed by the Federal authorities because of the presence of foot-and-mouth disease. He had been unable to find proof of the existence in this country for thirty years until the past winter of foot-and-mouth disease in cattle. The disease was characterized in the bovine animal by an aphthous eruption in the mouth and upon the less hairy portions of the skin. Dr. Brush said that in Lawrence, Mass., he found a family, a mother and five children, who consumed three quarts daily of milk afterward discovered to come from cows which had foot-and-mouth disease. The three-year-old child who lived almost exclusively on milk suddenly became ill with fever, vomiting, and diarrhœa; the tongue became much swollen and covered with blisters and the child had convulsions almost daily. Just then it was learned of the disease among the cows supplying this milk, and the children so affected in this family promptly recovered on stopping the milk. This, indeed, was the only way of making the diagnosis in ordinary practice.

(To be continued.)

## BRITISH MEDICAL ASSOCIATION.

*Seventy-first Annual Meeting, Held at Swansea, July 28, 29, 30, and 31, 1903.*

**Special Report to the Medical Record.**

(Continued from page 272.)

### SECTION OF TROPICAL DISEASES.

*Thursday, July 30—Second Day.*

**Trypanosomiasis.**—Sir PATRICK MANSON, K. C. M. G., opened the set discussion on this subject. He sketched very briefly the history of the discovery from Nepveu to Castellani and remarked that, as prognosticated a year ago, the subject of trypanosomiasis was taking an important place in tropical pathology. This important discovery and the great progress it had made in about eighteen months were due principally to the establishment of schools of tropical medicine and to the formation of a section on tropical diseases at the meetings of the British Medical Association. Indeed, had it not been for these schools and the section on tropical medicine, human trypanosomiasis would not have been recognized perhaps for many years to come.

1. *Methods of Investigation.*—In examining blood in the tropics several distinct kinds of parasites had to be kept in view: filaria embryos, trypanosomes, malaria parasites, spirilla, and bacteria. To find or exclude these it was necessary to make use of three degrees of magnification besides various methods of treating blood films. It was, moreover, important that the observer be intent on finding the particular form of organisms he was in quest of. He had, so to speak, to focus his mind as well as his microscope, otherwise he was almost sure to fail in his quest. For searching blood for trypanosomes it was best to use a moderately thin, fixed, methylene-blue, or better, thionin or Romanowsky-stained film and a $\frac{1}{6}$-inch objective. Very generally trypanosomes were scanty in the peripheral blood, and many slides might have to be searched before a single parasite was encountered. It was probably best to make the blood examination when the body temperature was high.

2. *Clinical Features.*—In the native, judging from some of Dutton's cases, *Trypanosoma gambiense* might give rise to no symptoms. In the European, an irregular undulant fever seemed to be a constant feature. Apparently the initial rise of temperature was high. Another probably very frequent symptom was the peculiar circinate erythema, together with accompanying œdema of the skin and subcutaneous tissue. Muscular weakness, rapid irritable pulse, anæmia, and breathlessness were fairly constant; enlargement of the spleen was very pronounced in some cases, absent in others. What might turn out to be a valuable point as an aid in diagnosis was the occurrence of eye symptoms (choroiditis, iritis, cyclitis, optic neuritis). Doubtless as we become more acquainted with the disease additional clinical phenomena would come to light. An important one might or might not be mononuclear leucocytosis.

3. *Possible Relationship of Human Trypanosomiasis to Trypanosomiasis in the Lower Animals and to Certain Obscure Tropical Diseases* (sleeping sickness, kala-azar, and certain forms of tropical splenomegaly).—The future would probably show that both *Trypanosoma gambiense* and the malarial parasites had other mammalian hosts in addition to the human mammal, and that these humbler mammals had a good deal to do with the endemicity both of trypanosomiasis and of malaria. More systematic and more extended observations were needed to clear up this point for both classes of parasites.

A most important question had been opened by Castellani's discovery of a trypanosoma in the cerebrospinal fluid in sleeping sickness. Was its presence there merely a coincidence, or was a trypanosoma the cause of sleeping sickness? The principal facts in favor of regarding the trypanosoma as the cause of sleeping sickness were (1) the frequency of its occurrence in this disease at all events in Uganda, and (2) its occurrence in connection with the nervous system. Now frequency of occurrence might only mean frequency of concurrence. Before concluding, on the ground of concurrence, in favor of the trypanosoma as the cause of sleeping sickness we must have accurate statistics as to the presence or absence of the parasite in the general population of the endemic area of sleeping sickness and, also, as to the geographical ranges of the disease and of the parasite respectively such an investigation had disposed of the claims of *Filaria perstans*, once so hopeful. As regarded the significance of the presence of the trypanosome in the cerebrospinal fluid too much importance must not be attached to this, for it was not improbable that it occurred in many of the fluids of the body besides the blood. Against the specific relationship of the trypanosoma to sleeping sickness were the facts that the European, so far, had not been attacked by sleepin sickness, although undoubtedly he must have often been the subject of trypanosomiasis and that so far the parasite had not been found in sleeping sickness on the Congo or in West Africa. The former objection might be explained by the assumption, suggested by Castellani, that the trypanosome hitherto found in Europeans was a different species to that found in sleeping sickness. This was a very improbable thing considering that, as Europeans get one kind of trypanosome on the Congo they might just as well get the other kind which Castellani's hypothesis postulates must occur there also. A great but not insuperable difficulty in the acceptation of the view that the trypanosome was the cause of sleeping sickness lay in the fact that in some, perhaps in many, instances, the interval between the date of infection with the specific cause and the clinical manifestation of the disease was one of several years. Although in many specific infections prolonged incubation periods occur (for example, in leprosy, tuberculosis, rabies, etc.), so far as was known, successful infection with trypanosomes was manifested within a few days or weeks from its occurrence. It was difficult to conceive how a pathogenic agent like a trypanosome could remain inactive for periods amounting to years. In conclusion, Sir Patrick said, "I am inclined to the view that the trypanosoma of the African is not the cause of sleeping sickness." On the other hand, he expressed the

hope that in the *Trypanosoma gambiense*, or in a similar parasite, we might find the explanation of kala-azar and of those curious and very fatal forms of chronic fever, not amenable to quinine and accompanied by enlargement of the spleen and liver and after by hyperpigmentation of the skin.

*Prophylaxis.*—The prophylaxis of trypanosomiasis would be surely indicated as soon as it was known what was the inoculating agent. It might be a *glossina*, a *tabanus*, a *stomoxys*, or other blood-sucking diptera; but there were other blood-suckers in Africa besides diptera, more particularly ticks, which should not be overlooked. The Carrapato disease of the Zambesi basin was certainly produced by the bile of a tick, *Argas monbata*. This disease was probably more widely distributed than was generally known. Sir Alfred Sharpe, H. M. Commissioner in British Central Africa, came across this disease near Lake Tanganyka. Whether the Carrapato disease had any thing to do with the trypanosome or not, it certainly belonged to that great group of tropical diseases that depend on infection by insects and their allies.

**The Human Malady, Trypanosomiasis.**—Drs. J. EVERETT DUTTON and J. TODD read a paper with this title, in continuation of the discussion. They had investigated trypanosomiasis in Gambia. They examined over 1,000 persons and found the parasite in six natives and one white man (quadroon). The history and clinical examination of the native cases revealed nothing important. In the younger cases, the usual enlargement of the spleen was met with. Enlargement of lymphatic glands was present in some, but not in others; parasites were very scanty. The disease, as it occurred in natives, was a peculiarly mild one. Possibly the black man in this disease bore the same relation to the white as did the game of Central Africa to domestic animals in the tsetse-fly disease. The various ages of the natives infected indicated that their could be no acquired immunity.

Several animals were examined for trypanosomes, but the parasite was found only in horses. Out of thirty-six horses examined ten were infected. The symptoms noticed were: loss of vigor, periodical rises of temperature, marked emaciation, and, at times, a slight watery discharge from the eyes. The animal wore an apathetic, chronically tired expression, which was most characteristic. In none of these horses did they observe the marked œdemas and the changes in the coat described as characteristic of the tsetse-fly disease. There was a general enlargement of all lymphatic glands. Several experiments of inoculation into the lower animals were made, both with *Trypanosoma gambiense* and with the horse trypanosome. These experiments showed a distinct difference in the diseases produced in animals by the human and by the horse trypanosome. The horse parasite was the more pathogenic. The condition resulting from infection with the human trypanosome was very chronic, the animal's health did not seem to be affected, and in the only deaths which had occurred of animals infected with this parasite no macroscopic lesions were perceived. In the early stages of both diseases the continued presence of the parasites in the peripheral blood was far from the rule. This tendency to disappear from the peripheral circulation was much more marked in the human parasite. In the later stages of the horse disease (a week before death) the presence of parasites was constant, and their numbers gradually increased until death occurred. The morphology of the two parasites presented no characteristic differences. Therefore it was impossible to decide whether the parasites found originally in the horse and man were the same or different. The one clear distinction that could be drawn at present was the marked dissimilarity of the disease produced by inoculation in the lower animals. The authors had tried many times in vain to transfer both parasites by biting flies to healthy rats from either naturally infected horses or artificially inoculated animals. Two species of flies, *stomoxys* and *glossina*, were used. If the method of transmission of this disease were, as some maintained, simply a mere mechanical transference of parasites from one animal to another by means of the insect's proboscis they would have been successful. They suggested that perhaps the parasite could live for even a few hours in the insect's proboscis during the dry season, owing to the excessive lack of moisture in the atmosphere. Mr. Hewly, a traveling commissioner in North Nigeria had informed the writer that his ponies passing through a certain bit of bush in the wet season often became ill and died of fly disease. Ponies sent through the same bush in the dry season, however, escaped, although the flies, which he said were the same as the glossinæ they showed him, were always present in great numbers.

**Sleeping Sickness in Relation to Trypanosomiasis.**—Dr. CHRISTY followed with a paper with this title. He went to Uganda as one of the members of the sleeping-sickness investigation commission sent by the Royal Society. He found that sleeping sickness was not distributed all over Uganda and Busoga as reported, but was strictly confined to the northern shores of Lake Victoria Nyanza. Indeed the disease did not extend for more than ten miles from the shore. Cases beyond this limit were very rare; and the patients had always a history of having come from the lake shore. The disease occurred in a narrow strip along the coast line from the Kotanza river right across to Kissumo, there it skipped a small portion and then extended to the Gori river. It would appear that the disease was spreading rapidly eastward. It had been reported as prevalent on the west of the lake, but he had met with only two cases there and both came from the islands. The affected area included all the islands, many of which were very seriously infected. The disease showed no tendency to spread either inland or along the Nile and its tributaries. He found that there was no connection between *Filaria perstans* and sleeping sickness, and reported this to the Royal Society as early as October, 1902. He came to this knowledge by examining blood of natives every ten miles on his journey. In parts *Filaria perstans* was very prevalent, but as he traveled eastward the percentage fell from 60 to 14, then to 5, and over Kavirondo and near the German boundary no *Filaria perstans* was found. Sleeping sickness extended about 150 miles beyond the extreme limit of *Filaria perstans*. As to a possible connection between sleeping sickness and tsetse flies he was bound to say that he had not met with any species of tsetse that was troublesome. Sleeping sickness prevailed chiefly amongst agriculturists in the bush. Towns and populous centers were not affected much. He made a trip to Buvuma Island, which was severely affected, and there mapped all cases in the places in which they occurred. The dots on the maps showed that the distribution of the disease on the island corresponded to the general distribution of sleeping sickness. It was confined to the coast line overgrown with bush, chiefly bananas. M. Kavirondo, a comparatively treeless region, the sickness was found only in those parts in which there was bush. Having become acquainted with the fact reported by Austen that the tsetse fly had a particular dislike for fæces, he was inclined to connect the freedom from sleeping sickness of all large villages in Uganda and Busoga with the fact that the tsetse fly avoided the neighborhood of villages.

As to a possible connection between sleeping sickness and trypanosomiasis, he would like to mention that one of the occasional symptoms in sleeping sickness was an inordinate appetite. There was a peculiar craving for food up to the very last. This was also a symptom of trypanosomiasis in the horse.

**Tick Fever in Uganda.**—Dr. CHRISTY then read a second paper with this title. He had come across the disease first at Toro in Uganda, and subsequently found that it was fairly common in Buddu, Busoga, Uganda, Unyoro, and also on the Nile. The tick which caused the

disease was called *bibo* by the natives. Mr. Pocock of the Natural History Museum recognized it as identical to that long known to be pathogenic in the Zambesi valley: *Ornithodoros monbata*.

Dr. Christy described the symptoms of the disease which he had observed in one of his servants. These were: fever, violent headache, vomiting, and purging. He was never bitten himself. He always took the precaution of encamping far from native habitations and thus went through his travels without a day's illness. On examining the blood of the servant who had contracted tick fever, he found embryos of *Filaria perstans*. This made him think that very probably *Ornithodoros monbata* might be the intermediary host of *Filaria perstans*.

Dr. Aldo Castellani said that Sir Patrick Manson's observations on sleeping sickness were very important, but he was bound to confess that Sir Patrick's criticisms did not shake his opinion that sleeping sickness was a trypanosoma disease. As early as in the beginning of November, 1902, he began to find very frequently in Uganda a trypanosome in the cerebrospinal fluid of patients suffering from sleeping sickness. In twelve cases of other diseases taken as controls, he never found the parasite in the cerebrospinal fluid, and these controls came from the same districts as the sleeping sickness patients. His results had been amply confirmed by such an authority on trypanosomes as Colonel Bruce, who, using the same technique, found the parasite constantly. He would not discuss whether the trypanosome present in sleeping sickness was identical with *Trypanosoma gambiense* or not, because, according to Dutton, Todd, and Manson, *Trypanosoma gambiense* was not pathogenic to natives. The trypanosome of sleeping sickness must be different if not morphologically, at least by its biological properties, as pointed out by Dr. Sambon. But the question of species was a secondary one; the important point was whether the trypanosome present in sleeping sickness was the cause of the disease or not.

He did not think that the clinical features of sleeping sickness were against the trypanosoma theory. He agreed with Sir Patrick that the symptoms of sleeping sickness were different from those of the trypanosomiasis due to *Trypanosoma gambiense*, but he could not understand why there should be in man only one form of trypanosomiasis when there were five in the horse, namely, nagana, surra, malde caderas, dourine, and the new form just described by Dutton and Todd.

As regards the pathological features of sleeping sickness, he did not think that they were against his theory. The mononuclear infiltration around the vessels of the brain, and the mononuclear exudation in the cerebrospinal fluid, were certainly more in favor of a protozoal infection than against it.

Dr. L. W. Sambon said the information supplied by Dr. Christy as to the presence of *Ornithodoros monbata* in Uganda, Busoga, and Unyoro was very interesting, but the confirmation of the peculiar disease inoculated by this tick was especially valuable. Formerly the "disease of Tete," described by Dr. Livingstone and Sir John Kirk, was somewhat doubtful, but now we were in possession of sufficient information to show that it was undoubtedly a specific and widely distributed tick-fever. Dr. Emile Brumpt had told the speaker that the natives of Kilimandyaro and the Galla country feared the bite of a tick, which they asserted caused disease in about eight or ten days. It was probably *Ornithodoros monbata*. As to the association between *Ornithodoros monbata* and *Filaria perstans*, Dr. Sambon thought it very improbable. Dr. Christy had not found *Filaria perstans*, or any other kind of filaria, undergoing development within the body of the tick, and the very different geographical areas of *Ornithodoros monbata* and *Filaria perstans* were strongly against the hypothesis that *Ornithodoros monbata* might be the intermediary host of *Filaria perstans*.

As to the trypanosoma theory of sleeping sickness, Dr. Sambon said he considered it exceedingly probable. Sir Patrick Manson objected that the long incubation period of the disease was against the trypanosoma theory. Dr. Sambon failed to see why. There were examples of a long incubation period or of a long latent stage intervening between the moment of infection and the manifestation of grave symptoms in several diseases, and chiefly in diseases known, or believed to be due to, protozoal parasites (malaria, blackwater fever, sprue, hydrophobia, etc.). On the other hand, we must admit that although at times the incubation period of sleeping sickness might be very long; as a rule, it was comparatively short. A comparison between the clinical features of sleeping sickness and those of trypanosomiasis in various animals was very favorable to the trypanosoma theory of sleeping sickness.

As to the distribution of sleeping sickness and its probable connection with tsetse flies, Dr. Sambon thought that Dr. Christy's observations, coupled with the observations and experiments made by Drs. Dutton and Todd in Gambia, were very much in favor of the suggestions he had recently published in the *Journal of Tropical Medicine:* He thought that tsetse flies were not merely carriers of trypanosome infection, as stated by Lieutenant-Colonel Burce, but that they acted as intermediary hosts to these parasites. The peculiar development of the tsetse larva within the body of its parent suggested very strongly a transmission of the disease through the progeny, as was known to be the case in cattle hæmoglobinuric fever (Texas fever).

The patchy distribution of sleeping sickness along the margin of rivers and lakes seemed to agree very well with the peculiar distribution of tsetse flies. The trypanosoma theory of sleeping sickness suggested a *glossina* as the most probable intermediary host, and, though various species might prove efficient in the transmission of the disease, *Glossina palpalis* was most to be suspected on account of its wide range in West Africa. He thought that the well-known limitation of tsetse flies to the neighborhood of water bodies might find its explanation in peculiar feeding habits, connected with the fresh water fish of Africa, many of which are amphibious and live in burrows like rabbits during the long, dry season, coming out at night to feed on grain and insects. Trypanosomes were very common parasites amongst fish, and especially amongst those species which lived in the mud. It was also important to remark, with Laveran and Mesnil, that the trypanosomes of fish were strikingly like those of mammals, and very different from those of the more closely related batrachians. The natives of various parts of Africa (Senegambia, Congo), ascribed sleeping sickness to the sting of a fish, or to the consumption of diseased fish with swollen gills.

As to the relation between sleeping sickness and the trypanosoma fever described by Ford, Dutton, Manson, and Baker, it was at present impossible to state anything definite. Morphologically, he saw no difference between *Trypanosoma castellanii* and *Trypanosoma gambiense*, indeed it was not possible to distinguish either of these trypanosomes from those found in nagana and surra. But, of course, it was quite possible that they did represent different "strains" or, as he had suggested in his paper on sleeping sickness, different "biological species." Indeed, experimentally it had been shown that, passing through certain hosts, the trypanosomes of nagana acquired certain peculiarities which greatly modified their pathogenic action when again inoculated into their usual hosts.

G. C. Low, speaking of the question of *Filaria perstans* as a cause of sleeping sickness, said that when in British Guiana he had found *Filaria perstans* present in at least 50 per cent. of the aboriginal Indians, amongst whom he was convinced sleeping sickness did not exist. On arriving in Uganda, he found that Drs. Hodges and Wiggins had already shown that there were no cases of

*Filaria perstans* in Kavirondo, yet sleeping sickness was spreading there with great rapidity. It had been asserted that *Filaria nocturna* only sometimes gave rise to symptoms, and that *Filaria perstans* might do the same. A glance at the site of selection of the adults in the human subject showed at once that this did not follow. *Filaria nocturna*, living in the lymphatics, if it died, might give rise to changes in the lymphatic system, but *Filaria perstans*, living as it did in the connective tissue of the mesentery, could not. The only other theories would be a collection of embryos in the cerebral capillaries which did not occur, or the formation of a toxin which was excluded by analogy from the case of other *filariæ*.

In accepting a connection between sleeping sickness and trypanosomes, one must be careful. In the marasmic condition which patients passed into in sleeping sickness many parasites seemed to invade them. Post mortem they showed ankylostoma, Ascaris lumbricoids, Trichocephalus dispar, Bilharzia hæmatobia, Filaria perstans, evidence of old malaria, and now also trypanosomes. Until this could be admitted one must, in exactly the same way as for *Filaria perstans*, examine individuals in areas in whom there was no sleeping sickness, and also in areas in which the disease existed to see how many of the healthy individuals harbored this parasite.

From the pathological standpoint, the disease resembled closely a bacterial one, and the appearance of the meningeal exudation, if glanced at superficially, resembled closely that of an ordinary septic meningitis. On close examination one saw, however, that in sleeping sickness the exudation consisted of mononuclear leucocytes, and was seen spreading in the perivascular spaces around the vessels, whereas in the septic meningitis the exudation was polymorphonuclear, and was not seen spreading around the vessels. The chronic condition of the first disease might cause the mononuclear infiltration, but the point required clearing up.

Dealing with Dr. Christy's theory that *Argas monbata* was the host of *Filaria perstans*, though the tick-like bug was very common in British Central Africa, Daniels had clearly shown that there was no *Filaria perstans* there. Again in British Guiana there was no *Argas monbata* and yet *Filaria perstans* in abundance. Even assuming that filariæ were found in sections of an argas it did not follow that it had anything to do with the filaria one was searching for. To obtain reliable results on the subject of intermediate hosts one must always rear one's insects and then serially dissect them. If this were not done, one was liable to fall into grave errors.

As regards Dr. Sambon's statement that tsetse flies were always found near water, Dr. Low said he knew that there were large areas completely dry and covered with scrubby bush where they were common, but perhaps Dr. Sambon and he were talking of different species.

Capt. Leonard Rogers objected to the view of regarding kala-azar as a trypanosome-disease. He thought the recognition of trypanosomes by so-called involution forms was doubtful. He had examined several hundreds of cases of kala-azar, but had never found a single trypanosome. A characteristic feature of kala-azar was the peculiar melanotic pigmentation invariably found in the various organs; such a pigmentation was proof of an endoglobular parasite which destroyed the corpuscle. The trypanosome lived in the plasma. In surra no melanotic pigmentation was produced by the trypanosome.

**Abscess of the Liver.**—Fleet-Surgeon P. W. Bassett Smith, R. N., read a paper based upon the observation of five cases of abscess of the liver. In all five cases there was a history of dysentery, but in none had it been of a severe character. In two cases exploratory punctures failed to find pus which later burst upward through the lung. Blood examination showed a rising leucocytosis before operation and a rapid and steady fall after. He condemned operation by trocar and cannula and advocated the transthoracic method of reaching the pus.

Mr. James Cantlie of London discussed the same subject in a paper on "Ten Cases of Liver Abscess with Remarks on the Operation by the Trocar and Cannula and Syphon Drainage." Mr. Cantlie, from experience gained in the treatment of liver abscess in his own practice and in that of others, had come to the definite conclusion that the safest, most speedy, and most successful method of treatment was by the trocar and cannula and syphon drainage. He condemned the transthoracic method of reaching pus in the liver as too heroic, as unsuitable when the patient was far advanced in the disease, and except in well-appointed hospitals as a wholly unjustifiable step. For deep-seated abscesses in the liver, incisions, whether by way of the thorax or abdomen, in no way helped toward the determination of the situation of pus in the liver, and they hampered rather than helped toward obtaining subsequent safe and satisfactory drainage. The cases in which exploratory needle punctures of the liver had caused hemorrhage, Mr. Cantlie ascribed to wounding of the inferior vena cava. He maintained that this could be avoided by having a care not to puncture too deeply; for example, in a chest of 32 inches circumference at the seat of puncture, it was not safe to penetrate more deeply in a direction toward the inferior vena cava than 3¾ inches. Of the ten cases reported by Mr. Cantlie three were suprahepatic abscesses, one was a subhepatic abscess and six were intrahepatic. The intrahepatic abscesses were all subsequent to dysentery; the other patients had not had dysentery. Two patients were lost by the operation, having been deferred to too late a period, pyæmic organisms being already present in the blood at the time of the operation. The others recovered. Early exploration in suspected cases of liver abscess, operation by the trocar and cannula and syphon drainage for all deep-seated abscesses of the liver Mr. Cantlie maintained was a simple, satisfactory and successful method of treating pus in the liver.

Capt. Leonard Rogers, I.M.S., read a paper on "Biliary Abscesses of the Liver with an Operation."

*Friday, July 31—Third Day.*

**Leprosy: Its Etiology, Histology, and Treatment.**—Mr. Jonathan Hutchinson, F.R.S., opened the discussion. He said that an overwhelming body of evidence was opposed to the belief that leprosy spread by any ordinary mode of contagion (the breath, touch, clothes, bites of insects, wounds, etc.). No one in any way connected with lepers in asylums ever contracted the disease. Numbers of lepers came to England, or went to America, and yet they did not spread the disease. He thought that commensal communication—that is, by eating food contaminated by a leper's hands—did occur occasionally, but was by no means frequent. In India sweetmeats were often sold by lepers. In India and Norway lepers were employed as fruiterers and bakers. It had been suggested that the acarus of scabies might be concerned in the transmission of leprosy. Scabies was very general amongst lepers, but it was not a means of communication, neither were any insects. The belief in contagion was based merely on the discovery of a bacillus in leprosy. Facts were opposed to it. It was rare to find the disease both in husband and wife. With the exception of a very doubtful case, all inoculation experiments had failed to reproduce the disease. Hereditary transmission, if it ever occurred, was certainly a rare event. The transmission of the disease from mother to child was one of commensal communication by the milk. In all countries where leprosy was not common the great majority of the cases arose *de novo*, in the sense that their had been neither inheritance nor any exposure to risk of contagion. All facts pointed to some article of food as the cause of

leprosy. But there was only one article of food which could be reasonably suspected, and that was fish. The excessive prevalence of leprosy in certain fishing districts was a fact strongly in favor of the fish hypothesis, and the excessive incidence of the disease in Roman Catholic communities supported the same conclusion. It was the badly cured and decomposing fish that was the cause of the disease. Improved methods in the salting of fish had greatly reduced the incidence of the disease in Norway and other countries. The amount of circumstantial evidence now accumulated on the fish theory of leprosy was sufficient not only to justify, but to demand that measures based upon it should be adopted.

Dr. H. MARCUS FERNANDO stated that his experience in Ceylon was opposed to Mr. Hutchinson's views.

Mr. JOHN D. HILLIS, F.R.C.S., said his own experience of leprosy extended over twenty years as visiting physician to a large leper asylum in British Guiana, and it was directly opposed to Mr. Hutchinson's. In British Guiana there were several tribes of aboriginal Indians, all of whom lived by fishing, hunting, etc., and consumed large quantities of salted or fresh fish. Leprosy was unknown among any of these tribes, except the Warraus. The latter, who were not so exclusive as the other tribes, alone of all of them dwelt near and commingled and intermarried with the lepers when the asylum was removed to the mouth of the Pomeroon, and leprosy had prevailed among them ever since, whilst the other tribes had remained absolutely free. If fish caused leprosy among the Warraus, Mr. Hutchinson would have to explain why the others are exempt.

Dr. PHINEAS S. ABRAHAM of London expressed his thanks to Mr. Hutchinson for again bringing this important question forward. He for one was greatly troubled by Mr. Hutchinson's final appeal against those terrible leper prisons like Robben Island. While he thought that bad cases, which could not be properly treated—with due precautions—at home, should be sent to special hospitals, it seemed monstrous to confine patients in the early stages. Although he agreed with Mr. Hutchinson in many respects and could confirm his statements especially as regards the absence of evidence of contagion in this country, he believed that leprosy was a bacillary disease, and that like tubercle, it could be introduced into the human system—but with more difficulty—by various channels, the alimentary and respiratory systems, and also by inoculation through the skin. He was in this sense a contagionist. The ground opened up by Mr. Hutchinson was so wide, that it would be impossible now to discuss all the points raised. He deplored the resuscitation of the term "*de novo*"—it seemed to him inaccurate to say that a disease which was known to have a definite bacillary cause ever arose *de novo*. Mr. Hutchinson believed that improved methods of fish curing were the real cause of the rapid decrease of leprosy in Norway since the enforcement of partial segregation. The speaker would read a letter received from Dr. Ehlers, the great Scandinavian authority on leprosy, which answered this point.

Dr. Ehlers said, "Why does he (Hutchinson) always speak of badly cured fish, when he speaks of the fish-theory? What is 'badly cured' and what is 'well cured' fish? There must be in the fish something (bacillus, poison or what?) which causes leprosy, if his idea is right. It is not possible to fight with so ill-defined terms. He must give a better explanation of what he means with 'badly cured.' In Norway and Iceland the methods of curing (that is to say of drying) fish are now the same as a century ago, but the people of to-day are cleaner than those of the eighteenth century and it is clear that the fish is treated more carefully. In Iceland there was an increase of leprosy from the moment (1848) the four small and poor asylums were closed to the years 1894–1895, when I made my first investigations in that country and convinced the Icelanders of the danger of contagion. The Icelandic leprosy law of the 4th of February, 1899, and the opening of the Odd-fellows Leper Asylum with seventy beds at Reikixvik have already—within five years—caused a remarkable decrease in the number of cases of leprosy. In 1896 I found in Iceland 181 lepers and presumed that there were over 200 (we now know that this was really the case). The latest report from Dr. Bjarnhedinsson, just published (July 10, 1903), shows us that this number had decreased at the begininng of the year to 133, *a decrease of one-quarter in five years!* Do you think that the fish has been better cured in these five years? I think that the opening of the hospital, with isolation of seventy of the worst lepers, has been the chief cause. At the same time 4,000 copies of my popular pamphlet on leprosy were spread amongst the population. In twenty years leprosy will have disappeared from Iceland, as it is disappearing in Norway and Sweden.

"In the so-called fish-hypothesis there is another obscure point. Mr. Hutchinson speaks in a general way of 'badly cured fish,' but the different populations amongst whom this old theory still prevails believe that only particular species of fish are able to give the disease. Thus the Icelanders incriminate the halibut or the trout. On the Agean Sea, the inhabitants of the Pelion fear the tunny. In the Danish West Indies the negroes speak of the king-fish. Does Mr. Hutchinson mean that all kinds of fishes can give leprosy, or has he any suspicion against certain species? How can he explain the development of leprosy in people who have never eaten fish? I have seen such people in Crete. In my eyes there is only one grain of truth in the fish theory. The people who content themselves with badly cured dry fish are very poor people. Such poor people are always very dirty, and filth is the mother of contagion."

Dr. F. SANDWITH of Cairo said that his experience in Egypt gave no support to Mr. Hutchinson's fish theory.

Sir PATRICK MANSON said Mr Hutchinson appeared to him like one of the old prophets preaching to the wilderness—no one would listen to him. He thought enough had been said about the fish theory. The data on which it was based were insufficient and did not bear critical investigation. Like tuberculosis, leprosy was a bacillary disease and a contagious disease.

Dr. L. W. SAMBON said Mr. Hutchinson recognized the Lepra bacillus as the cause of leprosy, but he ascribed the production of the disease to the consumption of badly cured fish. His statements were somewhat contradictory. He adduced much information to show that the specific bacillus was frequently swallowed with impunity with fruit, sweetmeats, and other foodstuffs handled by lepers with open sores, indeed he reminds us that inoculation experiments had practically always failed; and, at the same time, he expected us to believe that the disease was contracted by eating fish that had been salted, dried, and cooked. At one time he thought that fresh fish might cause leprosy, now he seemed inclined to look upon leprosy as a form of food poisoning etiologically analogous to that caused by decomposed canned meats (kreotoxismus). The peculiar geographical distribution of leprosy; its study increases in certain regions, its steady decrease in others; its disappearance from many parts of Europe where it was prevalent at one time; its sudden appearance and rapid spread in islands and countries previously immune, were all facts which did not agree with Mr. Hutchinson's theory. It was quite true that the discovery of the Lepra bacillus had prompted the belief in contagion. The term "contagion" was an old, misleading term. Recent knowledge had shown how very varied were the ways and means by which a disease could pass from one person to another. As a rule, there were intermediary agents of transmission, and very probably the peculiar conditions of leprosy infection would find their explanation in some necessary intermediary agent. Dr. Sambon fully agreed with Mr. Hutchinson and Dr. Abraham as to the horrors of segregation in leper asylums, but he was bound to admit that

it was owing to the cruel, pitiless measures of segregation enforced during the Middle Ages that leprosy had been almost swept out of Europe. To avoid much more wretchedness in the future, it was of the utmost importance to deal wisely with present lepers. It was not yet known how the disease was transmitted; it was quite possible that man might derive the infection from some lower animal, as he might contract tuberculosis from cattle, and plague from the rat, but there was no doubt that another leprous man was the usual source. It was known for a positive fact that each patient might become a center for other groups of cases. It was known also that the disease had always decreased under the influence of segregation. We must therefore restrict the wandering of lepers in order to prevent a wider spread of this fearful, incurable disease.

**Plague in Domestic Animals.**—Mr. JAMES CANTLIE of London drew attention to the announcement recently made that in the Hongkong market two fowls, a duck and a quail, had been found infected by plague. Coming as it did in connection with the experiments of Professor W. R. Simpson and Dr. Hunter, in Hongkong, in the direction of proving that plague was readily communicable to lower animals, the information was at once interesting and significant of marked danger to any community in which plague appeared. The experiments of Simpson and Hunter went to show that fowls, ducks, turkeys, geese, swine, buffalo calves, goats, etc., were highly susceptible to infection when given food contaminated in any way by plague. Many of these animals had plague, with high temperature, etc., without exhibiting any sign of illness. A pig, for instance, would go about apparently quite well with a temperature of 103° to 104° F., and not until the fourth or fifth day would any indication of disease become apparent—generally only a few hours before death. Mr. Cantlie contended that the infection of domestic animals constituted even a graver danger than that of rats, as they were frequently in intimate contact with the natives in their dwellings. The danger of taking on board ships fowls, pigs, sheep, etc., infected by plague was very pronounced, seeing that these animals exhibited no symptoms of being ill. He thought that whilst we had been fighting against contamination by the rat we had omitted to notice that the domestic animals around us were also infected by plague.

### SECTION OF MEDICINE.

*Friday, July 31—Third Day.*

**Susceptibility and Infection.**—Dr. R. J. M. BUCHANAN of Liverpool opened this discussion. Three types of infection were distinguished, the purely bacterial, the toxic, and a combination of both. Examples of natural immunity were instanced, as in animals of different color and species and in persons of different race, and of different age period. The function of the skin, lympathic glands and other structures in preventing infection were referred to, and the protective substances characteristic of natural and acquired immunity were differentiated. Investigations by himself in relation to phagocytosis were described in which observation on the protective influence of the leucocytes in leucocythæmic blood—in regard to anthrax and typhoid bacilli. Hardly any infectious disease had a chance of gaining a lodgment in the body, unless there were a lowering of the natural resistance from some cause or other. Anything which caused hyperleucocytosis increased the bodily resistance. The natural resistance to poisons had had demonstration—for example, in the case of the pig and hedgehog in relation to snake poison. Reduction of bodily resistance from starvation was discussed, also from unsuitable diet, from the exposure to heat, cold, and damp, and fatigue, from traumatic lesions, the removal of organs, particularly the pancreas, and from the injection of chemical bodies and others. Mixed infection was then discussed; it was pointed out that pure tuberculous infection was slow and the tendency was to recovery, but if other organisms, particularly the streptococci, were implanted then the disease tended to run a rapid course and the chance of recovery was slighter. Artificial or acquired immunity was lastly referred to, including reciprocal infections between the bacilli and the host. It was suggested that the toxic effects of bacilli might depend on the stimulating effect of the irritating substances produced by their otherwise harmless action in disturbing the metabolism of the body. It was suggested that an endotheliolysin might play an important part in rheumatic fever, explaining the association of cardiac disease.

Dr. MACPHEDRAN of Toronto asked if the natural resistance of an individual were proportional to bodily vigor; it seemed, as for example in the case of typhoid fever and smallpox, that it was not. He referred to the antagonism of streptococci to malignant disease, and raised the question whether sarcomata were due to infective organisms. The apparent immunity of children fed on mother's milk might mean that they were better nourished than those fed on cow's milk.

Dr. D. C. MCVAIL of Glasgow also had found that persons who had been most violently attacked by infectious disease were the most robust physically, indicating that some unknown factor apart from so-called vital resistance might be concerned in the establishment of immunity.

Dr. Buchanan, in reply, said that robustness, from the clinical point of view, must be distinguished from specific resistance, and alluded to the cure of tuberculosis by an intercurrent attack of erysipelas.

**Formaldehyde in Tuberculosis.**—Dr. CHOWRY MUTHU of Wells then read a paper on the treatment of tuberculosis by formaldehyde as a supplement to the sanatorium method, in which he referred to the methods of inhalation, of intravenous injection, and of cataphoresis. He had healed 25 cases by intravenous injection, generally giving 50 c.c. of a 1 in 1,000 solution. In a few cases the improvement was, he considered, striking, but it was combined with the open-air treatment.

Dr. BUCHANAN approved of formaldehyde inhalation for consumption; he considered it a valuable remedial agent. He had found a good method of administration was to sprinkle a few drops of a 40-per-cent. solution on a handkerchief from which it was inhaled. He spoke unfavorably of the intravenous method.

**Bronzed Diabetes.**—Dr. G. PARKER of Clifton then reported a case of bronzed diabetes with an account of the necropsy and of the microscopic pathological appearances in the liver, spleen, and pancreas. The suprarenal capsules were healthy. He maintained that the disease was more nearly allied to hypertrophic cirrhosis, splenic anæmia, and pernicious anæmia than to diabetes.

**Spinal Puncture in Uræmia.**—Dr. D. C. MCVAIL of Glasgow read a paper on this. He attributed uræmic coma to increased intracranial pressure due to œdema of the brain. Removal of an ounce of cerebrospinal fluid was followed in two cases by rapid and general improvement.

**Temperature in Phthisis.**—Dr. T. N. KELYNACK and Mr. SYDNEY WILLIAMS then communicated a paper on the relative value of rectal and oral temperatures in the management of phthisical cases. The records of temperature taken during rest gave much more satisfactory and reliable indications than those taken during or shortly after exercise. In 45 per cent. of the cases the rectal and oral temperatures corresponded, but in 38 per cent. they materially differed, and in these the disease was slight. Rectal temperature during rest were usually higher, but did not afford any special advantage as compared with the oral method during rest, and with due care the oral method seemed to afford an altogether reliable guide.

Dr. W. B. JONES read a paper on "The Mineral Waters of Llangammarch Wells."

# Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 15, 1903:

| | Cases. | Deaths. |
|---|---|---|
| Measles | 125 | 8 |
| Diphtheria and croup | 295 | 26 |
| Scarlet fever | 86 | 2 |
| Smallpox | ... | ... |
| Varicella | 12 | ... |
| Tuberculosis | 282 | 145 |
| Typhoid fever | 96 | 12 |
| Cerebrospinal meningitis | ... | ... |

**Milk Combs.**—According to the *Scientific American*, there were exhibited at the Hygienic Milk Supply (Hygienische Milchversorgung) Exhibition, by the Vereinigten Gummiwaren-Fabriken of Hamburg and Vienna, combs and cigar holders made of milk, or rather of "galalith"—*i.e.* milk stone. An advantage the new product is said to possess over celluloid is that it does not ignite so easily and is without scent.

**Hog Cholera in the Philippines.**—Dr. Richards, veterinarian of the Board of Health, was the first to suspect the presence of this disease in Manila hogs. With his assistance a number of the killed hogs were subjected to autopsy and bacteriological examination. The characteristic lesions of the disease were found and the "bacillus cholerae suis" isolated from the spleen and lymphatic glands of several of the cases.

**Cost of London Smoke.**—M. J. C. Hawkshaw, the engineer, is of the opinion that $25,000,000 a year is not an excessive estimate for the total expense of smoke pollution to London.

**The Race Suicide Question in Germany.**—There would seem to be no fear that a decline in the birth rate will soon be witnessed in Germany—that is to say, if all German mothers are as fruitful as those of Berlin. It has been recorded recently that one hausfrau of that city, although but forty-five years of age, has already twenty-eight hale and hearty children. Another, who is younger by four years, has brought twenty-three into the world, while yet three other women between the ages of forty and forty-three have presented their husbands with twenty-one descendants each. There are said to be two hundred and forty Berlin women who are the mothers of from thirteen to twenty children apiece.

**An Early Advertisement of Jenner's Vaccine.**—The *Scientific American* for July contains this interesting piece of old-time news. It says that a little more than a hundred years ago Dr. Jenner announced his discovery of vaccine as an alleviator of smallpox. The following is a verbatim copy of that call published in the London *Times* which was signed by about one hundred of the medical profession, scientists, members of Parliament, and the nobility: "London, January 10, 1803. The invaluable Discovery of Dr. Jenner, for the Extermination of Smallpox, having undergone the most rigorous investigation, and received the sanction of Parliament, a meeting will be held at the London Tavern, Bishopsgate street, on Wednesday, the 19th inst., at twelve o'clock, to consider the best means of carrying the same into effect, when the company of every gentleman disposed to concur in this laudable undertaking is earnestly requested. The Chair will be taken by the Lord Mayor precisely at one o'clock."

**Subjects for Anæsthesia.**—Dr. Hewitt divides his difficult and bad subjects for anæsthesia into six classes: (1) Patients whose general health is good, possibly exceedingly good, but who possess some physical peculiarity rendering them more or less liable to intercurrent embarrassment or arrest of breathing. (2) Patients whose respiratory tract is in some way encroached upon or whose respiration is in some way hampered by pathological or other conditions. (3) Patients suffering from certain grave visceral or constitutional affections. (4) Highly nervous or excitable patients, those suffering from various nervous affections; and those who have been addicted to the excessive use of alcohol, tobacco, morphine, or other drugs. (5) Patients displaying, in a state of combination or association, the characteristis of two or more of the foregoing classes. (6) Patients who prove to be difficult or bad subjects without any discoverable cause.—*The Hospital.*

**Baby Shows—a Suggestion.**—A London contemporary has fallen foul of fat babies, or rather has been endeavoring to awaken mothers to the fact that because an infant carries a large amount of adipose deposit it is not necessarily healthy. In the course of its remarks the *Lancet* says: "It is a matter of clinical experience that a fat baby is unhealthy, with little resistance to disease, and likely to succumb on the least provocation to any of the so-called minor ailments of infancy. It is very greatly to be regetted that baby shows, if they are to be held at all, cannot be utilized for educating the laity to admire in babies those "points" which are genuinely deserving of admiration and expressive of a physiological condition, instead of acting as they do, as direct inducements to over-feeding with foods which fatten but do not produce sound healthy tissues.

**How It Feels to Be Chloroformed.**—The lately deceased British poet, essayist, and critic, W. E. Henley, when a patient at Edinburgh Infirmary for operation, thus vividly and realistically describes the process then practised of administering chloroform, and the sensations of the one operated upon:

"You are carried in a basket,
Like a carcass from the shambles,
To the theater, a cockpit,
Where they stretch you on a table;

"Then they bid you close your eyelids
And they mask you with a napkin,
And the anæsthetic reaches,
Hot and subtle through your being;

"And you gasp, and reel, and shudder,
In a rushing, swaying rapture,
While the voices at your elbow
Fade—receding—fainter—farther.

"Lights about you shower and tremble.
And your blood seems crystallising.
Edged and vibrant, yet within you,
Racked and hurried back and forward.

"Then the lights grow fast and furious,
And your hear a noise of waters,
And you wrestle, blind and dizzy,
In an agony of effort

"Till a sudden lull accepts you,
And you sound an utter darkness,
And awaken—with a struggle—
On a hushed, attentive audience."

**Deterioration of Microscope Lenses and India-rubber Goods in Hot Climates.**—The following is from a paper on the "Preservation of Instruments in Bengal," read by Mr. Paul Bruhl before the Calcutta section of the Institution of Electrical Engineers on March 27 and printed in the London *Engineer* of July 24: One of the most powerful corroding agents employed by nature is carbonic acid. We are accustomed to look at carbonic acid as a weak acid . . . but when the acid is more concentrated under the action of high pressures the action is markedly different. Now capillary action has a similar effect on concentration as a large increase of superincumbent pressure; and the carbonic acid present in the film of moisture which covers all articles during the rainy season, or in the film separating two surfaces in apparent contact, is in a much more concentrated state than corresponds to the atmospheric pressure. Such carbonic acid is capable of displacing the silicic acid of natural and artificial silicates. . . . Microscopists know how difficult it is to keep

a stock of blank glass slides. If you keep your glass slides in contact with each other they are sure to grow dim . . . sometimes even if placed in alcohol. An absolutely safe plan is to tie two threads round each separate slide near its two ends, form a number of slides into bundles and keep them in alcohol or formalin. . . . The worst place to keep microscope objectives in during the rainy season is the cylindrical brass case provided for them by the makers. Microscope lenses—in fact, lenses and glass parts in general—do not stand close confinement for any length of time. Constant use is the best preservative. In any case place the lenses in a capacious box and air them frequently. . . . Some of the modern kinds of glass have to be tended very carefully . . . otherwise they will soon become dim evenly all over their surface. . . . The best way of keeping rubber stoppers is to put them into a wide-stoppered glass jar, at the bottom of which is placed an inverted perforated dish to serve as a support for the stoppers after pouring some oil of turpentine on the bottom of the jar. Stoppers which have acquired a hard cracked surface can be softened by proceeding similarly, only using chloroform instead of turpentine. A good way of preserving rubber tubing is to give it a coating of glycerin.—*The Lancet.*

**How He Paid His Doctor's Fee.**—Kinjiro Yoshimura' thirty-six years of age, rentee of a house in No. 6 section, Asakusa park, a man of no definite occupation, or, to be more accurate, a professional gambler, is a chronic sufferer from asthma. For some time back he had been in the habit of calling at Dr. Hara's in his neighborhood whenever a fit of coughing came over him and of being relieved of his suffering by opiate injections. On such occasions he was given liberty to stay and rest for a full day or two in an inner room of the doctor's house, and when well to leave it for his own home at any hour of day or night that suited his convenience. While this sort of thing had been going on without any hitch on the one hand, Detective Sanada of Asakusa police station had found out, on the other hand, in the course of his official rounds of the pawnbrokers that this same gambler had, since January last, been drawing certain different sums of money from a pawnshop on the pledge of articles of various description, including silk dresses, which aggregated in value over 150 *yen*. The question of whence these articles came finally led to the man Yoshimura's arrest, on last Thursday afternoon. According to the confession which the fellow has since made to the police, it appears that each time he went to Dr. Hara's to be treated for his asthma, which was genuine, and had a full rest in the manner above described, he made a point of stealthily taking away with him some property of the doctor, that he found within easy reach, and of changing his booty for money at the pawnbroker's. All the money he had thus obtained he had spent, to use his own unblushing confession, in paying the doctor his professional fee!—*Sei-I-Kwai Medical Journal.*

**Bacteria of Water of Public Swimming Baths.**—A paper was read on this subject by Dr. Glynn and Dr. Matthews at the annual congress of the British Royal Institute of Public Health, held recently in Liverpool. The authors said that investigation showed that salt-water baths contained fewer bacteria than fresh water. According to observations they had made, it was found that the water in a first-class bath removed from the skin and hair of each bather in about ten minutes approximately 4,000,000,000 bacteria. In the second-class bath each contaminated the water with 6,000,000,000 bacteria. One source of contamination besides the human body was dirt, which was carried into the corridors by the shoes of bathers, and he suggested that the ideal swimming bath of the future should have two corridors, one of which should be used solely by bare-footed people. There was no evidence that bacteria in swimming baths was injurious, yet, if they occurred in large numbers, it proved that the water was not clean, and, to put it mildly, cleanliness was the essence of hygiene.

**Radium and Its Lessons.**—Sir Oliver Lodge, writing on radium in the July issue of the *Nineteenth Century* and after, in summing up, says, "and let me conclude by asking readers to give no ear to the absurd claim of paradoxers and others ignorant of the principles of physics, who, with misplaced ingenuity, will be sure to urge that the foundations of science are being uprooted and long-cherished laws shaken." Nothing of the kind is happening. The new information now being gained in so many laboratories is supplementary and stimulating, not really revolutionary, nor in the least perturbing to mathematical physicists, whatever it may be to chemists, tor, on the electric theory of matter, it is the kind of thing fhat ought to occur. And one outstanding difficulty about this theory, often previously felt and expressed by Professor Larmor—that matter ought to be radio-active and unstable if the electric theory of its constitution were true—this theoretical difficulty is being removed in the most brilliant possible way.

**Effect of Formalin on the Skin.**—The cuticle is killed; it hardens, cracks, and desquamates; in some individuals this is attended by an eczematous rash. The nerve terminals in the skin are paralyzed, producing an annoying numbness. Where the skin is cracked the entrance of formalin becomes very painful.—W. H. DALL in *Science.*

**Health Report.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended August 15, 1903:

SMALLPOX IN THE UNITED STATES.

### THE SYPHILITIC AFFECTIONS OF THE HEART AND AORTA.*

BY LEONARD WEBER, M.D.,
NEW YORK.

IT was in 1895 that I had the honor of reading a paper on "Syphilis as a Factor in Diseases of the Heart and Lungs," before this association. The literature of syphilis of the heart has grown very considerably since that time, and there have been so many publications of carefully observed cases that there is no further doubt among the well-informed as to the frequency of its occurrence in the later stages of syphilis. When Fournier and Erb, in the seventies of the last century, called the attention of the profession to the frequency of disease of the nervous system attributable to the toxins of syphilis, their observations were soon corroborated by other clinicians, and it was not more than ten years thereafter that this highly important knowledge became the common property of not only the neurologist, but the general practitioner as well. Thanks to the labors of Virchow, Heubner, and many others, we have learned and are now convinced of the fact that syphilis may be counted as rather frequent among the various causes of arterial degeneration, in the form of sclerotic and gummatous processes, leading to endarteritis obliterans, with its baleful influence upon the nutrition of the parts supplied by the diseased vessel. Forty years ago this was not known, and the heart, of all organs, was looked upon as practically exempt from syphilis; now we are recognizing that sclerosis of the coronary arteries, softening and degeneration of the cardiac muscle observed in persons under fifty years of age, are often of syphilitic origin, and it will not be long, I believe, before physicians in general will admit that syphilis of the heart is not infrequently seen in persons who have or have had syphilis.

In considering the etiology and general pathology of cardiac syphilis, the first question which would present itself is this: is there a predisposition on the part of certain luetic patients, so that they are more apt to develop cardiac syphilis than others? In a paper read before the New York Academy of Medicine, published in the MEDICAL RECORD, April 5, 1884, on "Syphilis and Locomotor Ataxia," by which the discussion of the interesting subject was started and kept up for a number of years in various medical societies in this country, I showed that of 125 cases of syphilis, treated by me and observed for a period of from fifteen to twenty years, there were but two who presented marked symptoms of specific disease of the brain (hemiplegia) and died of it, and that these were two men who, for one reason or another, could not be convinced that they had syphilis and, unfortunately, abandoned treatment during the first year of observation. Not one of the whole number had tabes. It is much the same, probably, with cardiac syphilis. In the first place then, a light case of syphilis, overlooked, not treated at all perhaps, or an ordinary case of syphilis treated in a perfunctory way, or not long enough, or when properly treated, becoming mixed up with alcoholism, is apt to develop nerve or visceral syphilis in the course of time, sometimes not until many years after infection. Again it is a matter of frequent observation, and I have notes of some cases confirming this, that by the neurotic taint inherited or acquired by prolonged masturbation, or excess in venery, alcoholism, unusual physical stress and exposure, the syphilitic is predisposed to specific and degenerative changes of the nervous system; but similar influences may not as regularly produce similar results with reference to cardiac syphilis, and it will be shown by the history of a few cases that the vigorous have as little guarantee against coronary sclerosis and its baleful sequelæ as the feebly constituted syphilitic. Gout and lead poisoning may run alongside with syphilis producing their own lesions without influencing that disease in the direction of arteriosclerosis in any noteworthy way. There is, for instance, the case of M. C., aged fifty-four years, with hereditary gout, a free liver, vigorous, married rather too soon after acquiring syphilis, wife died some years ago showing signs of contamination; his son had hereditary syphilis. Now this man has had many attacks of gout in the last twelve years, during which he has remained free of all specific symptoms, but heart and arterial system do not yet give any appreciable sign of disease.

Whether there is any particular occupation predisposing the infected to specific heart disease more than any other, I cannot say, but will mention that the two most marked cases of specific disease of heart and aorta which have been seen by me concerned shoemakers, the younger of whom died suddenly the other day, while the older man is still alive and much improved by treatment.

It has been stated that in the course of tabes dorsalis, aortic insufficiency is occasionally seen to develop. That is true, but not in the sense that posterior sclerosis produced the disease, but that it is caused by the syphilitic virus so often associated with tabes. Having carefully watched the development of aortic disease, including valves in old syphilis, and without the presence of any other marked influences, I am convinced of the correctness of above statement. I also believe that I am able to show now a causal connection between the syphilitic toxins and certain cases of chronic diffuse and interstitial nephritis dependent upon arteriocapillary sclerosis of the kidney.

What do we find at the autopsy of a syphilitic heart or aorta? At the outset let me repeat what I said in a paper on this subject, read before the New York Academy of Medicine, March 9, 1899, and published in the *New York Post-Graduate Journal*, May, 1899: Excepting the gumma in the cardiac muscle or cardiac arteries, there is nothing in the appearance of the sclerotic changes of the vessels or in the softening and degeneration of muscular fibers that would enable us to distinguish the arterial sclerosis of syphilis from that made by other diseases. And it is even so with "Pulmonary Syphilis in the

*Read before the American Climatological Association at the meeing in Washington, D. C., May, 1903.

Adult," *vide* the excellent monograph under that title by Drs. Thomas E. Satterthwaite and W. H. Porter, published in the *Boston Medical and Surgical Journal*, June 11 and 18, 1891, wherein it is shown that the white pneumonia s. c. alone presents specific appearances. Read the essays on cardiac syphilis by Mracek, *Archiv für Dermatologie und Syphilis*, 1893, Vol. XXV, Is. Adler's observations on cardiac syphilis, *N. Y. Medical Journal*, October 22, 1898, and on arteriosclerosis in MEDICAL RECORD, and another paper by the reader on arteriosclerosis and chronic nephritis in the *New York Post-Graduate Journal*, April 15, 1898, and so on down to Professor Runeberg's recent résumé of the subject in the *Deutsche medicinische Wochenschrift*, 1903, Nos. 1 and 2, and you will find that, at a time when neither the aorta nor the main trunks of the coronary arteries exhibit any signs of disease, endarteritic and periarteritic processes may be developed in and about the smaller vessels of the heart, leading to structural changes later on.

The case develops further and we notice atheromatous patches in the aorta, pulmonary and coronary arteries, under the microscope endo- and periarteritis and interstitial myocarditis pretty well advanced. In another case again, with the symptoms of enlargement, weakness and arythmia of heart and dyspnœa during life, the dilated heart will show areas of softening (myomalacia) in the myocardium, streaks and patches of fibrous growth replacing muscular fibers, occasionally also a gummatous tumor. Again, when the symptoms have been those of angina pectoris alone, coarse lesions of the main trunk of the coronary artery only may be found after the sudden death of the sufferer. I may mention here the unusual case of a man aged forty-five years, who died some time ago of acute pulmonary œdema during an attack of ordinary bronchial catarrh in midsummer; he had had syphilis some twenty years before that, and the autopsy revealed extensive atheroma of the pulmonary artery extending way out into the ramifications of the vessel.

Through obliterating endoarteritis and periarteritis, distention of capillaries and smaller veins occurs sometimes and in addition thereto small hemorrhages take place, the extravasated blood forcing the muscular fibers apart and breaking them into fragments, as shown first by Ehrlich. To be sure, hemorrhagic infarction is not the usual way in which myocardic tissue is destroyed, but it is through deficient blood supply that the fibers undergo atrophy and molecular disintegration, and that scar-tissue is formed in their place by simple cellular infiltration; and replacement of numerous muscular ele ments by fibrous tissue means permanent impairment of vital function. This has an important clinical bearing, for it is evident that proper therapeutic measures may arrest further developments of morbid cell-proliferation and gummatous growths and produce absorption, but are powerless against fully developed fibrous tissue. The fact, then, is now established that, wherever structural lesions are found in the cardiac muscle, due to syphilis, there also typical alterations in the blood vessels can be made out; and there is good reason to believe that myocarditis and subsequent degeneration are secondary to the vascular lesions.

*Diagnosis.*—In the absence of syphilitic stigmata in a given case, it will be almost impossible to arrive at a correct diagnosis at an early stage of the disease. The differential diagnosis will also be difficult, particularly when the patient is unwilling or unable to give a satisfactory history of previous luetic disease. By careful attention to details in our examination, and *ex juvantibus* when other means fail, we shall, not infrequently, make the diagnosis of syphilitic lesion pretty certain.

Leaving the purely senile heart, which has a literature of its own, out of consideration altogether in this paper, it is evident that in endocarditis and myocarditis from rheumatism, in the alcoholic, the nicotine, the fatty, the gouty heart, syphilis may, as a rule, be excluded, though it may occasionally complicate one or the other of these forms of heart disease. The signs of myocarditis in individuals below fifty years, such as weak impulse with accentuated second sound, arythmic action, tachycardia, or even brachycardia, faintness, dyspnœa on exertion, angina pectoris, general depression and weakness, should always arouse our suspicion of syphilis, whether the patient admits a previous infection or denies it; in the absence of any other satisfactory etiology, we are justified to assume syphilis, and try to arrive at a correct diagnosis by specific treatment. The signs of active syphilitic lesions in other parts of the body in a case of myocarditis, would go far toward making the diagnosis certain. The treatment may fail to cure, as it will in a case of advanced fibrous degeneration; that does not disprove the syphilitic nature of the case; it may be too far advanced to yield to treatment.

Semmola contends that arythmia and tachycardia without other functional disturbances, not clearly to be accounted for on other grounds, and not yielding to the ordinary treatment with digitalis or other cardiac remedies, are pathognomonic of cardiac syphilis, and he reports a number of such cases cured by iodide and mercury, after all other treatment had failed.

The clinical and anatomical material is as yet insufficient to decide to what extent his views are borne out by actual fact. However, Isaac Adler, Wm. Thompson and myself reported such cases to the New York Academy of Medicine in 1898 and 1899.

Quite a number of cases of sclerogummatous disease of the coronary arteries manifest themselves mainly by the symptoms of angina pectoris. Professor Runeberg of Helsingfors states that a case of this kind, going on without cardiac hypertrophy and other symptoms of general arteriosclerosis, occurring in a patient under fifty years, is of specific origin at least eight times out of ten. When not relieved by proper treatment sudden death during an attack is not a rare event.

Next to specific sclerosis of the coronary arteries, in frequency and practical importance, must be placed syphilitic aortitis, with its sequelæ, degeneration of the semilunar valves and aneurysmatic dilatation. These affections of the aorta will be associated with cardiac hypertrophy and muscular degeneration also, particularly so when the valves are much diseased. Two very good examples of this kind I shall mention later on. The anatomical lesions found here are rather gross and generally more readily recognizable as specific sclerogummatous processes than those of the coronary arteries, other influences being excluded, the differential diagnosis is more readily made when the aortic disease concerns a person under fifty years of age, just as we know now that the majority of cases of aortic aneurysm present a previous luetic history. of my own records of about a dozen cases of aortic aneurysm, syphilis had been present in ten of these. Circumscribed gummata in the cardiac muscle are but rarely observed in comparison with arteriosclerosis and myocardic degeneration. When far-advanced obliterating arteritis is disclosed at the autopsy of a syphilitic heart, so that a small size

knitting needle only can be pushed along a coronary artery, and we know that nevertheless the patient had but few symptoms during life indicating serious cardiac lesions until he rather suddenly succumbed to a fatal attack, we can readily understand that a patient in the early stage of specific coronary sclerosis may present no symptoms whatever to indicate the presence of dangerous disease. And is it not even so in renal sclerosis and in endarteritis obliterans generally?

In the great majority of cases which have so far come under my observation, I have had pretty well marked signs of cardiac disease before me, but the heart can get along pretty well though its blood supply and muscular force may be reduced, and, provided we succeed in arresting further progress and cure by specific treatment, what may yet be curable, the prognosis is not so bad as it looks at first sight. Old cases may not be cured, but they can be greatly improved if they respond to treatment. I remember but one case concerning a young man with well-marked constitutional syphilis of recent date, with febris continua syphilitica, enlarged spleen, marked anæmia, and endomyocarditis, who got entirely well after mercurial inunctions, followed by the iodides and tonics, and has remained so these last four years. But this was a case of specific cardiac disease in the early stage, and in a young person.

To rely upon the iodides alone in the treatment of syphilitic heart disease will lead to disappointment, according to my experience; temporary improvement, often very good, you may get, but it will soon pass away; not so, however, if mercury be used with them or even without them, provided the patient's kidneys are sound. Then, and then only, will good and even permanent results be obtained in treating cardiac syphilis. For this purpose I have been in the habit of ordering mercurial inunctions whenever practicable; when not, the bichloride of mercury hypodermatically or the biniodide by the mouth. Advanced cases of syphilitic aortitis I have found less amenable to treatment than specific cardiac disease. The general nutrition of such patients is almost always much impaired and the various specifics are not well borne.

Finally, permit me to give the history of four rather interesting cases:

Case I.—Alb. M., aged sixty-seven years, father and mother lived to a good old age, and had always been well. Though a free liver and smoker, he was never ill until he contracted syphilis in 1877. He was carefully and sufficiently treated and kept under observation for six years. There have been relapses or manifestations of tertiary lues. He remained quite well and active until October of last year when he noticed his breath getting short on slight exertion, his sleep disturbed and uncertain, and his throat and trachea often filled with catarrhal secretions. The superficial dulness of heart occupied a somewhat increased area, impulse diffuse and weak, first sound poor, followed quickly by accentuated second sound, heart-pause shortened, arythmic, no murmurs. Marked sclerosis of radials, no angina symptoms. There seemed to be no doubt about the presence of chronic myocarditis having reached a stage at which the cardiac functions began to show serious disturbance. The question arose, was it all due to old syphilis, or also, perhaps even more so, to arteriosclerosis of advanced age, and the influence of liquor and tobacco? Tentatively, mixed treatment was ordered and carried out for four weeks, and an evening dose of digitalis was given, but the heart dimensions remained the same, the subjective symptoms improved but little. In December he experienced an acute attack of gastro-intestinal indigestion after eating some too rich or spoiled food. The patient had high fever for three days, on recovery felt very weak and had lost all appetite; presently he became dropsical, the water increasing with alarming rapidity, filling his legs, abdomen, and appearing in the pleural cavity, and the urinary secretion dwindled down to ʒ xv in twenty-four hours. He had lost all appetite, was somnolent without being able to sleep, had, in fact, all symptoms of venous back-pressure caused by rather acute dilatations of the right half of an already damaged heart. Specific treatment, calomel, strychnia, and moderate doses of fluid extr. digitalis failing utterly to afford relief, I said to myself: leave all previous history out of consideration and treat the case as one of acute incompensation. such as we observe sometimes in mitral regurgitation when the right heart becomes over-distended. Of an infusion of the best English leaves of digitalis, with citrate of potassium and tincture of columbo, he began to take a tablespoonful every three hours on a Wednesday noon, and in the night, from Friday to Saturday, he passed 90 ounces of urine. The re-established and increased diuresis kept right on, and after finishing a second bottle of same mixture in the course of the next five days my patient was not only safe, but practically well enough to go about. To this day, four and a half months having passed, he has been able to attend to business regularly, his pulse though good enough, continues arythmic, and his heart needs careful supervision, because it is and will remain the seat of chronic myocardic weakness and degeneration.

Case II.—Ad. M., aged sixty-eight years, married, father of healthy children, stout and active man. I have known him these forty years. He never had any of the usual signs of syphilis and would not admit he had it if I told him so to-day, but, fortunately for his welfare, I had noticed a well-marked superficial serpiginous syphilide over sternum about thirty-five years ago, when I happened to examine his chest. Eight years ago he came to me with well-marked symptoms of general neurasthenia, sense of heaviness and fatigue, somnolence, etc. Patellar reflexes were greatly reduced, pupils almost inactive, slight Romberg sign present. By a systematic course of hydrotherapy and rather perfunctory mixed treatment, repeated at appropriate intervals, he improved greatly, and had no occasion for further medication until three years ago when he came back and complained of dyspnœa, fulness in epigastrium, loss of appetite, weakness, etc. Finding the heart enlarged in all dimensions, an arythmic, small, jerky, fast pulse, and a greatly enlarged liver, I first put him on calomel for the purpose of unloading the viscera; this was done once a week for four weeks with very beneficial results in all respects. After that he took mixed treatment in moderate doses for fifteen days out of every month, and continued this for one year. His liver returned to almost normal dimensions, the cardiac dulness was much reduced; the progress of chronic myocarditis has been stopped, but, to be sure, no cure is to be expected. Digitalis has not been used in this case, though I tried it about a year ago, to reduce the size of an enlarged heart, but without any success whatever. Of great assistance in this and like cases are occasional purges by calomel or elaterium to relieve passive congestion and help thereby the action of such specific and other drugs as may be indicated.

Case III.—Mark M., aged sixty-three years, married, shoemaker, had syphilis between his twentieth and thirtieth years, which soon became latent.

Fifteen years ago he suffered from suppurating muscular gumma in leg which I scraped thoroughly with sharp spoon. Under iodoform dressing and mixed treatment, perfect healing took place. Last winter he came back complaining of cardiac symptoms. Heart somewhat enlarged, first aortic murmurish, ascending aorta dilated, slight angina symptoms, probably due to some coronary sclerosis and myocardic degeneration. Cardiac impulse weak, pulse arythmic, some œdema of lower extremities, slight albuminuria. By a course of iodide of potassium, strychnia and nitroglycerin, rapid amelioration of all symptoms was obtained, œdema and albuminuria disappeared, and patient is in fairly good condition at the present time.

Case IV.—Joseph K., aged thirty-seven years, married, shoemaker, father of healthy children, had syphilis when he was twenty-two years old, but knew of no more specific symptoms after twenty-five until about two years ago, when he was taken with severe neuralgia in the left side along the course of about the seventh intercostal nerve. He received treatment at various dispensaries and a hospital also. When he appeared at my clinic last October he was thin, pale, and worn, complaining of above pain mainly, and was in generally poor condition. By the fluoroscope the physical diagnosis of dilatation of heart and aorta was confirmed; there was muffled first aortic sound of aorta and an almost filiform pulse at left radial. Sacculated aneurysm of descending thoracic or arch of aorta could be excluded after repeated examinations, and the diagnosis confined to sclerogummatous disease of ascending aorta, and associated with disease of coronaries and myocardium, and syphilitic periostitis and neuritis concerning left seventh rib and intercostal nerve near the spine.

After a carefully conducted course of mercurial inunctions plus iodide of potassium his pains left him, and patient was able to work again at his trade, which he had not done for two years. During the summer he was put on tonics, and he kept on doing well until December of last year when his heart became weak again, general nutrition suffered, his intercostal pain returned, and angina pectoris symptoms occurred. Some improvement was had again after the iodides and cardiac tonics, but in March of this year the patient died rather suddenly during an attack of angina pectoris.

25 West Forty-sixth Street.

## PERITONITIS (PERITONEAL ADHESIONS) CAUSED BY MUSCULAR TRAUMA.

### THE TESTIMONY FROM AUTOPSICAL ABDOMINAL INSPECTION OF 350 ADULT MALES AND 135 ADULT FEMALES.

By BYRON ROBINSON, B.S., M.D.,
CHICAGO.

In this paper I wish to record some observations made during the last ten years in regard to muscular trauma causing peritonitis, and consequent peritoneal adhesions. Careful notes of 485 subjects were taken at each autopsical abdominal inspection. Local peritonitis (adhesions) has received the attention of noted writers, as Virchow, Rokitansky, Waldeyer, Langer, Treitz, Treves, Toldt, and many others, but, so far as I am aware, none has assigned muscular trauma as the cause of peritoneal adhesions.

Also autopsical abdominal inspection of some sixty children was made with preserved records. The object of this paper is to demonstrate that muscular trauma produces peritoneal adhesions (peritonitis), and that peritoneal adhesions compromise visceral function and structure, giving rise to disease and invalidism.

The location of peritoneal adhesions from muscular trauma are: (1) The ventral surfaces of the psoas muscle; (2) The ventral surfaces of the crura diaphragmatica; (3) The external lateral surfaces of the vertical cola; (4) Bilaterally on the distal surface of the diaphragm; (5) The proximal surface of the lavator ani and coccygeus muscles. If a segment of the tractus intestinalis lies within range of action of a strong muscle, like the psoas, the trauma of the muscle on the bowel segment, if pathogenic bacteria are present in the lumen, will induce the bacteria or their products to migrate through the tunica mucosa, through the tunica muscularis, and through the tunica serosa, whence peritonitis and consequent peritoneal adhesions arise. The migration of the bacteria or their products may leave no trace of inflammatory condition in the tunica mucosa or tunica muscularis.

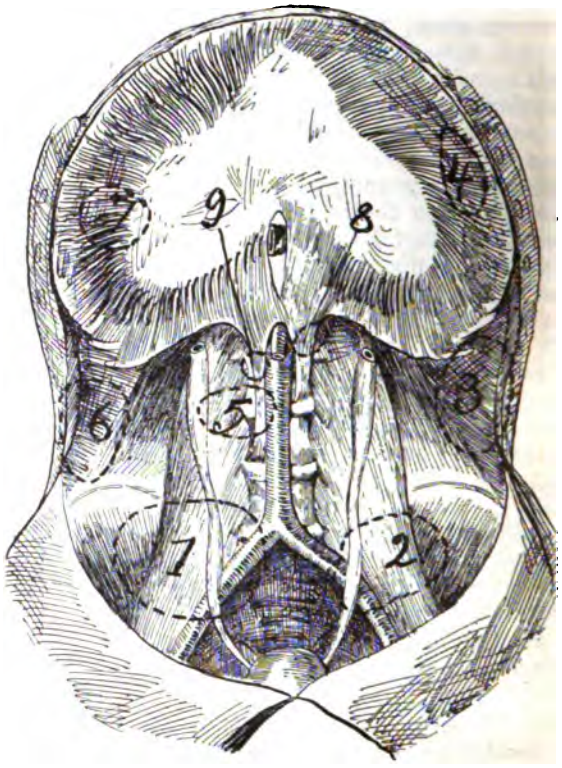

Fig. 1.—A cut of the abdominal muscularis to indicate location of peritoneal adhesions from muscular trauma; 1 and 2, ventra surface of the psoas muscles; 3 and 6, region along the vertical cola; 4 and 7, bilaterally on the diaphragm; 5, point where duodenum crosses psoas; 8 and 9, crura diaphragmatica.

Muscular trauma may also produce peritoneal adhesions adjacent to segments of the tractus urinarius, tractus genitalis, tractus vascularis, or tractus lymphaticus.

The location of peritoneal adhesions due to muscular trauma in order of frequence are: (1) Regio lienalis, 90 per cent., due to diaphragmatic trauma; (2) Regio flexura sigmoidea, 85 per cent., due to trauma of the left ileopsoas; (3) Regio ileo-cæco-appendicularis, 75 per cent., due to trauma of the right ileopsoas; (4) Regio pars duodenalis transversalis, 40 per cent., due to the trauma of the right crus of the diaphragm; (5) Regio peritonei minor, due to trauma of left crus of diaphragm; (6) Regio colidextra, due to left crus of diaphragm; Regio colidextra, 35 per cent., due to trauma of the right abdominal muscles; (7) Regio coli sinistra, due to trauma of the left abdominal muscles, partly; (8) Regio pelvica, due to trauma of the levator ani. The junction of mucosa and serosa of oviduct and peritoneum being unique requires

separate consideration. The most important damage of muscular trauma in causing peritoneal adhesions is on the appendix, the weakest segment of the tractus intestinalis, as the peritoneal adhesions disorder the function and structure of the appendix, obstruct its drainage, increasing the tension of

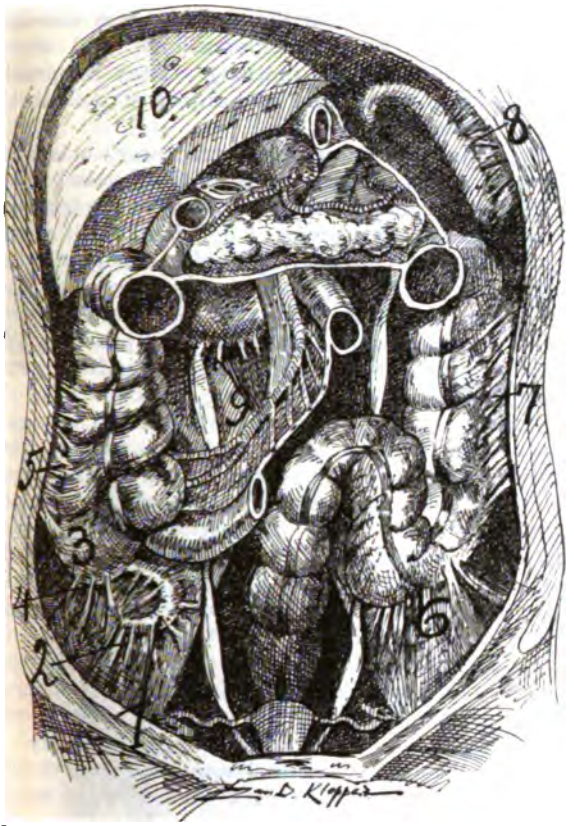

FIG. 2.—Illustrates peritoneal adhesions adjacent to the appendix (1 and 2); cæcum (4), vertical cola (5 and 7), mesosigmoid (6), spleen (8), transverse duodenum (9).

secretions in which bacteria multiply, and end in appendicular perforation—the most treacherous and dangerous abdominal disease. The following statistical statement of peritoneal adhesions presents the location and percentage found in 485 adult autopsies. The peritoneal adhesions are not all due

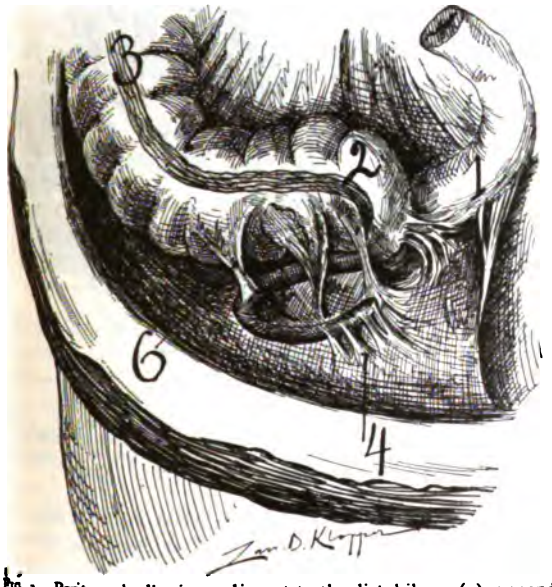

FIG. 3.—Peritoneal adhesions adjacent to the distal ileum (1), appendix (4 and 5).

to muscular trauma, but a large majority owe their existence to this cause.

Percentage of peritoneal adhesions found in 350 autopsies in adult males:

Appendix, 60 per cent.; cæcum, 60 per cent.; distal ileum, 50 per cent. Seventy-five per cent. exists adjacent to right ileopsoas.

Mesosigmoid, 85 per cent.; ligamentum entericocolicum, 55 per cent.; intersigmoid fossa, 80 per cent. Eighty-five per cent. exists adjacent to left ileopsoas.

Spleen, 90 per cent.; liver 44 per cent.; Haller's omentum, 45 per cent. Right crus of diaphragm.

Ligamentum phrenicocolicum dextra, 35 per cent.; ligamentum phrenicocolicum sinistra, 80 per cent.; ligamentum hepaticocolicum, 85 per cent.

Fossa duodenojejunalis, 30 per cent. left crus of diaphragm, 80 per cent. exists in the colon, the peritonitic or exudative area. Forty-five per cent. exists in the enteron. The absorptive or non-exudative area. Ninety per cent. exists in the tractus intestinalis.

Percentage of peritoneal adhesions found in 135 autopsies in adult females:

Appendix, 48 per cent.; cæcum, 55 per cent.; distal ileum, 40 per cent. Seventy per cent. exists adjacent to right ileopsoas.

Mesosigmoid, 80 per cent.; ligamentum entericocolicum, 45 per cent. Eighty per cent exists adjacent to left ileopsoas.

Spleen, 88 per cent.; liver, 60 per cent.; Haller's omentum 60 per cent. Right crus of diaphragm.

Ligamentum phrenicocolicum dextra, 52 per cent.; ligamentum phrenicocolicum sinistra, 45 per cent.; ligamentum hepaticocolicum, 80 per cent.

Fossa duodenojejunalis, 22 per cent. Left crus of diaphragm. Eighty per cent. exists in the colon, the exudative or peritonitic area; 40 per cent. exists in the enteron, the absorptive or non-peritonitic area. Eighty-eight per cent. exists in the tractus intestinalis; 75 per cent. exists in the tractus genitalis.

Muscular trauma produces maximum peritoneal adhesions when a segment of the viscus (especially of the tractus intestinalis) is fixed within the widest range of action of a long powerful muscle, *e.g.* the psoas muscles. The most striking example is the flexura sigmoidea, fixed to the left psoas muscle. It cannot evade the muscular trauma of the left

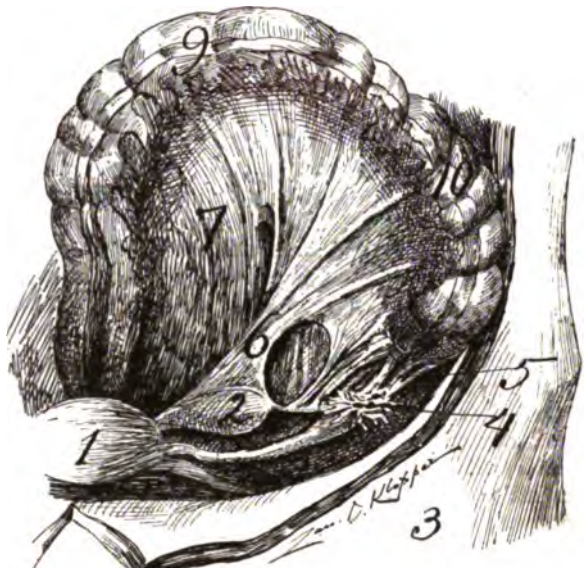

FIG. 4.—Peritoneal adhesions (5 and 6) connecting the ovary (2) and oviduct (4) to the mesosigmoid (7)

psoas, because it is fixed closely adjacent to this muscle—hence, mesosigmoiditis, recognized as macroscopic peritoneal adhesions, exists in the proportion of 80 per cent. The trauma inflicted on a dislocated segment of the tractus intestinalis while within the hernial ring and sac induces infectious invasion through the bowel wall and consequent peritoneal adhesions. The trauma arises from the clinching hernial ring, from the violent dragging of viscera, from the excessive and disordered peristalsis, and from the intense congestion. The trauma of hernia may rapidly cause desquamation of peritoneal endothelia and produce consequent atria for bacterial invasion.

In the autopsical abdominal inspection of sixty children I found practically no peritoneal exudates from muscular trauma in those who had not walked, and practically none in those under three years of age.

The muscular trauma of parturition produces peritonitis (exudates) not only by forcing infectious material into the cavum peritonei through the oviducts, but also by rupturing pathogenic cysts.

The elevation of temperature in a menstruating girl is due to infectious invasion of the peritoneum

through vigorous peristalsis of the oviduct or trauma of the levator ani muscle.

As the union of mucosa and serosa is unique in the oviduct the mucal pavilion being an intraperitoneal viscus, the explanation of peritoneal adhesions at the oviducal infundibulum must be unique and exclusive; however, the muscular trauma of the levator ani favors the passage of infectious material through the oviduct into the peritoneal cavity. Besides, from rapid development of the endosalpinx at puberty and during menstruation, the pavilion becomes everted into the cavum peritonei actually making it an intraperitoneal organ. Muscular and visceral rest during acute pelvic peritonitis rapidly limits the process.

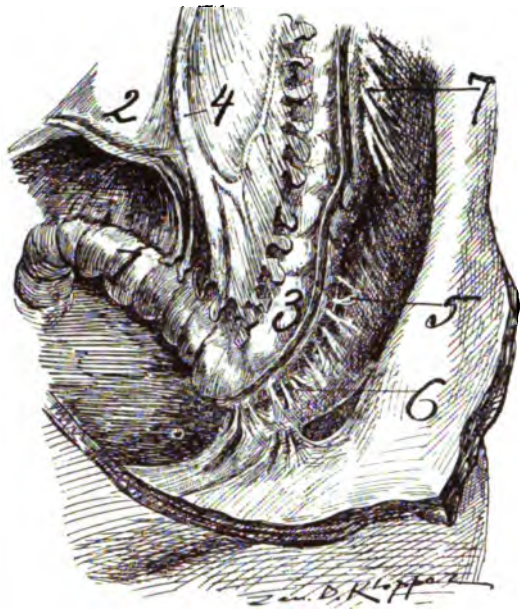

FIG 5.—Illustrates peritoneal adhesions (5, 6 and 7) between the left colon (3) and the lateral abdominal muscles

*Conclusions as to the Results of Peritoneal Adhesions.*—Peritoneal adhesions cause about one-third of all obstruction of the tractus intestinalis. Peritoneal adhesions disorder the common function—peristalsis, secretion, and absorption—of five abdominal visceral tracts, viz., tractus intestinalis, genitalis, lymphaticus, urinarius, and vascularis, by inducing excessive, deficient, or disproportionate secretion, absorption, and peristalsis—ending in insufficient elimination and malnutrition. They derange the special function of the tractus genitalis, viz., menstruation and gestation ending in dysmenorrhœa, abortion, and sterility. They damage the function of the tractus nervosus by traumatism; sensation and motion are disorderly and dragging, compression and dislocation end in pain and neuroses.

Peritoneal adhesions distort the structural mechanism of all abdominal viscera, *i. e.* the six visceral tracts by traumatism, dragging, compression, dislocation, angulation, and compromised lumen. The mechanism being deranged, impinged nerves will cry with pain and malnutrition must prevail. Peritoneal adhesions compromise the canalization of the five abdominal visceral tracts, obstructing drainage.

Peritoneal adhesions in one visceral tract, *e. g.* the tractus genitalis, reflects disorders the function of other visceral tracts. The irritation from the peritoneal adhesions, *e. g.* in the tractus genitalis, is transmitted to the abdominal brain, solar plexus (a reorganization center) over the hypogastric and ovarian plexuses, where it is reorganized and emitted to all other tracts, *e. g.* to the tractus intestinalis, producing excessive, deficient or disproportionate secretion, absorption, and peristalsis.

Peritoneal adhesions may produce chronic catarrhal inflammation of segments of the tractus intestinalis, especially of the appendix.

Peritoneal adhesions impair the object of the tractus intestinalis (digestion), tractus urinarius (urination), tractus genitalis (reproduction), tractus lymphaticus (cell nourishment), tractus vascularis (oxygen and food transportation), and tractus nervosus (control of function). They compromise the function, structure, and object of these six abdominal tracts.

Peritoneal adhesions in the tractus vascularis and lymphaticus by compromising the vessel lumen produce areas of excessive fluid congestion (excessive nourishment), and areas of deficient fluid, anæmia (deficient nourishment). Besides, congestion and anæmia compromise the tractus nervosus. They produce obstruction to visceral contents by flexures, kinks, compression, traction, compromising the visceral lumen, checking drainage, inducing stagnation of fluids, and forming conditions for the multiplication of pathogenic bacteria. They signify disordered function, dislocated structure, impaired visceral object. Nervous trauma may induce a train of pathological symptoms, such as meteorism, indigestion, malnutrition, congestion, anæmia, pain, neurosis, invalidism. The finest training and the finest skill are required to differentiate between such symptoms and those arising from splanchnoptosia. The neuralgic condition must be studied.

An organ that is progressively dislocated by persistently contracting adhesions becomes distorted in mechanism, compromised in its channels of lymph and blood, and traumatized in nerve periphery. It becomes defective in nourishment and its devitalized state makes it a prey to the first virulent and destructive germ attacking it. This is especially true in the appendix. Peritoneal adhesions produce diseased viscera through a progressive vicious circle, a circular chain, each link of which is a superimposed trauma. The duration of the contraction of peritoneal adhesions may continue over many years. I have operated on cases in which obstruction of the tractus intestinalis had occurred within a month, others in eight months, again one in three years, and one continued seven years before complete obstruction occurred.

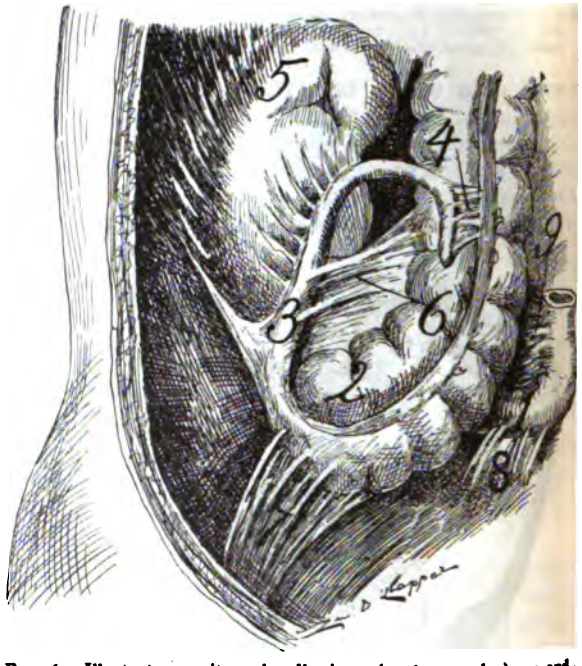

FIG. 6.—Illustrates peritoneal adhesions (4, 6, 7, and 9): 4 and 6 compromising especially the appendix, the weakest segment of the tractus intestinalis and which gives rise to the most treacherous and dangerous abdominal disease.

The fate of peritoneal adhesions is (1) absorption; (2) continuous contraction, which may obliterate its own vessels and cause it to disappear; the band may rupture in the middle or point of least nourishment; or the band may contract until it strangulates some viscus. (3) The peritoneal adhesion may be indifferent to the health of the subject.

The local abrasions of mucosa in the flexura sigmoidea, flexura hepatica, flexura lienalis, and flexura duodenojejunalis, due to trauma of passing foreign bodies increase the peritoneal adhesions in the region of muscular trauma as the mucous abrasions act as atria of infection in segments of the tractus intestinalis which are fixed and cannot evade muscular trauma.

The peritoneal adhesions which demand surgical intervention compromise highly mobile organs with active peristalsis, as the jejunum, ileum, oviducts, cæcum, appendix, sigmoid, and colon transversum.

Peritoneal adhesions from muscular trauma do not occur in infants or in children previous to walking, because the active muscular action of the erect attitude induces vigorous muscular trauma against visceral segments, especially that of the psoas against the ileo-cæco-appendicular apparatus and the sigmoid flexure.

Peritoneal adhesions dislocate viscera, as fixation is dislocation, and thus resemble splanchnoptosia.

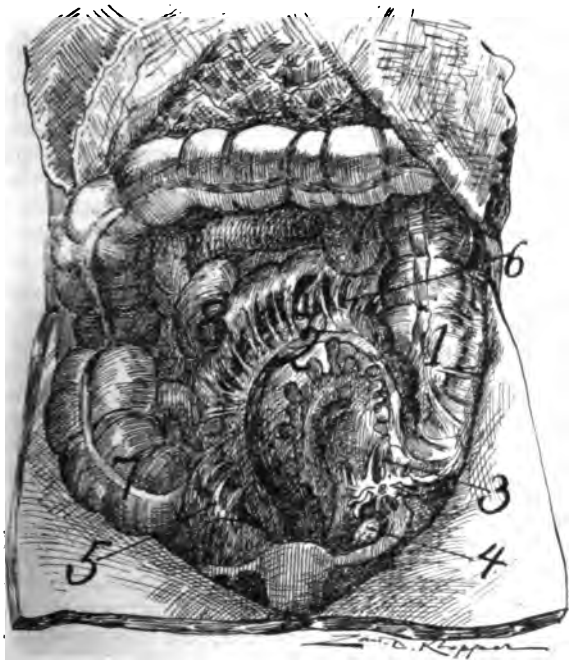

FIG. 7.—Illustrates peritoneal adhesions between the oviduct and mesosigmoid at (3); 6, extensive adhesions between the flexura sigmoidea (2) and the enteronic loops (8); 1, notes adhesions between left colon and abdominal wall; 5, notes adhesions between cæcum appendix, oviduct, and sigmoid.

Muscular trauma causes the main peritoneal adhesions to be located in the quiet vascular dorsal peritoneum, or especially the vascular mesenteries, as the active peristalsis of the segments of the tractus intestinalis does not allow time sufficient for the exudate to organize before it is crippled by absorption.

The symptoms of peritoneal adhesions do not indicate their character or location. Peritoneal adhesions from muscular trauma increase in frequency from twenty-five to sixty-five years of age. The track of infectious invasion from mucosa through muscularis to the serosa cannot always be traced. A healthy mucosa and muscularis may lie beneath a serosa extensively involved with peritoneal adhesions. A healthy serosa may overlie a diseased mucosa.

All organized peritoneal adhesions are covered on the surface by endothelia. Peritoneal adhesions are nature's method of protection and repair; peritonitis saves life while sepsis kills. A proof that muscular trauma causes peritoneal adhesions is that the adhesions are most numerous at the point where the muscular action has the longest range. The utility of peritoneal adhesions are: (1) they build barriers against infectious invasions; (2) they imprison, sterilize, and starve bacteria; (3) they are the great life-saving factors in acute inflammatory processes of the abdominal viscera, by preventing peristalsis from disseminating infection by obstructing the lymph channels leading from the infectious center; *e. g.* a subject recovers from relapsing appendicitis with increasing facility, because the lymph channels (stomata vera) leading from the diseased appendix are progressively obliterated.

---

## THE QUICK AND THE DEAD: A PLEA FOR URN BURIAL.

By W. J. CONKLIN, A.M., M.D.,
DAYTON, OHIO.

THE care of the dead as a sacred trust is recognized by all civilized peoples. The sentiment which underlies this trust finds expression in the effort to perpetuate the memory of the dead by the erection of costly monuments, and by the beautifying and adorning of the spots chosen for their last resting-places.

And yet, after thousands of years of trial and experiment, the problem of how to dispose of the dead without harm to the quick awaits a satisfactory answer. The gruesomeness of the subject should not cause it to be lightly pushed aside, for in many parts of the world its solution is a matter of serious import and involves questions of the deepest sanitary and moral interest.

Were we merely animal existences, in whom refinement and love did not exist, we might leave to nature the disposal of our bodies, and might lie and decay wherever we chanced to fall. "Of what consequence is it," says Plutarch, "whether one rots *in* the earth or *upon* it." But society and humanity have their claims. The one is obliged to remove the dead for its own comfort and safety; the other holds it a sacred duty to give decent burial to friend or foe.

Mortuary customs, reflecting the religious beliefs and superstitions of those practising them, not only form interesting and instructive chapters in the history of the race, but, in some instances, reveal the story of civilizations that rose and fell centuries before the Christian era.

In the disposal of the dead, four principal methods have been employed by nearly all nations, either simultaneously or at successive periods, in their progress from savagery to civilization. These are exposure, embalming, inhumation, and burning.

Exposure is the most primitive, and belongs essentially to the savage age. It is practised in a modified form by some of our Western tribes, the Blackfeet and Mandans; by the Ahts in Vancouver's Island, and by certain tribes in India, Central Africa, and South America. The most enlightened of those still practising this method are the Parsees of India, disciples of Zarathustra, and in many respects the most interesting and progressive sect in Asia. After solemn and impressive funeral ceremonies they place their dead on high stone platforms called *dakhma* or "towers of silence," where they are speedily destroyed by the flocks of sacred, but hungry vultures which, true to their instincts, haunt the vicinity. The bones are

afterward gathered by the friends and preserved in a large central well.

Of all modes of preserving the body from decay, embalming as practised by the ancient Egyptians has been the most successful. They carried the art to a perfection not since attained; and applied it not only to human beings, but to cats, crocodiles, and other animals held to be sacred. By an elaborate process of drying, salting, smearing with wax and honey, and stuffing with spices and aromatics, they produced a mummy, which, though it bore no resemblance to the original, was practically indestructible, and in modern museums, after the lapse of centuries, sermonizes to succeeding generations on the vanity of human aspirations.

"The Egyptian mummies," says Sir Thomas Browne, "which Cambyces or time hath spared, avarice now consumeth. Mummy is become merchandise. Mizraim cures wounds and Pharaoh is sold for balsams."

The origin of burning and earth burial is involved in obscurity. Both are of great antiquity. The latter came into general use with the advent of Christianity, and was the legitimate outgrowth of the doctrine of a literal resurrection and its attendant superstitions. The adoption of sepulture by the early Christians was undoubtedly encouraged by their hostility to all customs bearing the stamp of paganism and by the relentless persecutions to which they were subjected. It was necessary in order to escape the "official eye" that their burial rites should be conducted with greater secrecy than was possible with burning, and this necessity drove them to the catacombs, which served as retreats for the living as well as repositories for the dead.

Before the Christian era, nearly all of the nations of the old, and many of the savage tribes of the Western, world burned their dead with more or less pomp and pageantry. Cæsar tells that the Gauls not only burned, but cast into the funeral fire everything which the decedent held dear in life, even household pets and slaves.

The relics and sepulchral urns exhumed throughout Germany, Scandinavia, Denmark, and Great Britain testify to the prevalence of the practice in Northern Europe.

Marco Polo, who, toward the end of the thirteenth century, traveled extensively in China, found a rude crematory in every town. At the time of the conquest, says Prescott, the Aztecs burned their dead and preserved the ashes in ornamented urns in their dwellings. The pyre is still used in India, the interior of Japan, northwestern British America, and other parts of the world, reaching its utmost extravagance in Siam, where bodies of the royal family are burnt in wooden temples, elaborately painted and gilded.

The Greeks probably learned the art of burning on the pyre from the Phrygians, and in turn taught it to the Romans. A rich literature has made us familiar with the mortuary customs of these nations, to the tombs of which the world still goes for its funereal art.

At first, deemed by the Romans a high honor and only accorded to those distinguished in the field or forum, the pyre grew in favor as the nation rose in culture, and was never so much practised as in the reign of the Antonines, the period of Rome's highest attainments in philosophy and in the arts. The practice was discontinued in the reign of Gratian, near the end of the fourth century.

Homer has given us an imposing description of the rite, which in its essential features accords with the common practice of the Greeks and Romans. The scene is a military camp before the walls of Troy. The wearied troops are sorrowfully gathered around their bivouac fires, for Patroclus, the flower of the warriors, has fallen by the hand of the crested Hector. The body, its gaping wounds filled with precious ointment, anointed with oil and wrapped in fine linen, lies in state in the tent of his foster brother, Achilles. At dawn, under orders from Agamemnon, King of Men, the army proceeds to build out of fragrant fir and balsam the mighty pyre, a hundred feet in length and of equal breadth. The body of Patroclus is laid upon the pile and affectionately covered with the amber hair of Achilles and the locks of his faithful Myrmidons. With it are placed the fat of a score of oxen, twelve fiery steeds, the heads of two favorite hounds, and the bodies of twelve Trojan captives, slain in honor of the occasion. During the chanting of threnodies the torch is applied, and the flames leap to their devouring task. The oil and wine and honey give an uncanny appearancce to the flame as it mounts higher and higher on the huge pile. Now and then the clouds of black smoke which hang over the weird scene are cut by the wind into fantastic shapes, and form wondrous silhouettes against the sky. All night long the work of destruction goes on, and the morn discloses naught but a mass of glowing embers. These are quenched with red wine. The sacred ashes are separated and placed in the golden urn given to Achilles by his mother. The sad rites ended, the army gives itself up to races and games.

Modern scientific cremation has a short history. It had its re-birth in Italy, where its prototype died out 1,600 years before. The burning of the poet Shelley and his friend Williams (1882), by Lord Byron and Leigh Hunt in the sad fulfilment of a promise, on that lonely but picturesque Italian shore where the sea reluctantly gave up their shipwrecked bodies, and of Henry Laurens (1792), the second president of the Continental Congress, are the only instances in Christian lands which connect the old practice with the new. Although the subject began to attract the attention of modern scientists in 1867, but little progress was made until Professor Brunetti of Padua exhibited a model furnace with the results of his experiments at the Vienna Exposition in 1873. The movement, promptly endorsed by the leading sanitarians of the world, soon took on practical shape. England (1874) was the first to organize a national society for disseminating information on the subject, but so violent was the opposition of state and clergy that the furnace built at Woking in 1879 stood idle until 1885.

In contrast with the conservatism of Old England stands the progressiveness of New Japan, whose strides in civilization are the marvel of the century. It is estimated that nearly 50 per cent. of this nation's dead are incinerated; 10,000 being annually disposed of in the six public furnaces of Tokyo alone.

The first public crematory in Europe was built at Milan, Italy, in 1874. The first in the United States and the third after the renaissance, was established by Dr. LeMoyne, at Washington, Pa., in 1876. There are now in this country alone, not including those in medical colleges, 28 incineratories in successful operation, one-half of which have been built within ten years. The total number of incinerations in the United States to December 31, 1900, was 13,281 (Roever). It will be a surprise to many to be told that more voluntary cremations are made in the United States than in any Christian land of the world, Germany being a fair second.

The modern incineratory is an artistic building

with its chapel, reception rooms, and columbarium After such memorial services as the friends may elect, the body is committed to a specially constructed retort of fire clay, through which is passing air heated from 1,500 to 3,000° F. The body is oxidized, or reduced to its ultimate elements by means of this superheated air. The result is ordinarily obtained in from one to two and one-half hours, and so perfectly that from four to eight pounds of pearly white ashes, clean and odorless, represent all that was mortal of man. These may be harmlessly buried, or preserved in park, mausoleum, church or columbarium, as the wishes of the decedent or friends may determine.

The words "burning" and "cremating" are harsh and misleading, and are responsible for much of the popular prejudice against the reform. The ancients burned or cremated; the moderns oxidize or incinerate. To incinerate a human body means literally to reduce it to bone ash by extreme heat (2,000° F.) in a closed or partially closed chamber, and there is nothing to detract from the solemnity of the final leave-taking, or to add one pang to griefs already too great.

The problem to be worked out in furnace or grave is the same; to reduce the lifeless body committed to it speedily and safely, to its ultimate elements. Nature's plan, whether we will or not, demands this reduction. It is the inexorable law of life upon the earth. The moment the body is committed to earth, aye, even before its committal, subtle and complex molecular changes begin. Brain and muscle and bone fall by a degenerate metamorphosis into the simpler carbon, hydrogen, nitrogen, into acids, bases and inorganic salts. Oxygen, once the giver of life, now plays the rôle of the destroyer, and in the end nothing remains of the wonderful organism to distinguish it from its inorganic tomb. "Dust thou art, and unto dust shalt thou return."

Every atom thus set free from the bodies of animals, God-like man with the rest, by a fiat of the Creator goes unerringly to minister to the needs of other organisms. Now plant, now animal, the eternal cycle goes on. We "bury the dead out of our sight;" we dissipate the body with heat; we desiccate man into a mummy, but in no case do we defeat nature's law. It is a question of mode and time, not of results. Incineration only anticipates nature. The magician Fire does in a brief hour what the subtle chemistry of decomposition, under the most favorable conditions, takes years to do.

But it is not a question of mere sentiment. Here, as in many an other instance, nature's method is not the best, and is attended with danger to the living. This proposition, if true, places the necessity for radical changes in our burial methods beyond controversy, and to its proof we now pass.

In discussing this phase of the subject, I do not propose to draw harrowing pictures of the horrors of the grave. The gruesomeness of leaving our bodies in the ground, tricked out with posthumous funeral vanities, slowly to putrefy and be food for worms, is felt keenly enough by all.

"But that I am forbid to tell the secrets of my prison house.
I could a tale unfold whose lightest word
Would harrow up thy soul; freeze thy young blood;
Make thy two eyes, like stars, start from their spheres;
Thy knotted and combined locks to part,
And each particular hair to stand on end."

Neither do I wish to exaggerate the dangers to be apprehended from cemeteries. While I believe, with Sir Henry Thompson, "That no dead body is ever placed within the earth without in some degree polluting the soil, the water and air around it," I am equally positive that with a strict observance of known sanitary requirements and with favorable surroundings, the danger can be greatly lessened and sometimes safely ignored. The fact, however, that these requirements are rarely perfectly fulfilled in large cemeteries, and that in many, on account of the local conditions, it is impossible to do so, is too evident to need discussion.

That decaying organic matter, animal and vegetable, is inimical to health, is an elementary fact in sanitation, and is fully recognized by our municipal laws. From the evil effects of earth-burial we have no protection save that which comes from the purifying chemistry of the soil. Ordinarily when bodies are committed to earth, singly or sparsely, this power will suffice to render them inoffensive and harmless, but it utterly fails when men are stricken down in masses, as in pestilence and battle, and when, from any cause, overcrowding of the dead takes place. A long catalogue of epidemics attests the fallacy of relying upon soil filtration to remove impurities from water supplies. With an excess of polluting material, soil saturation soon occurs, and from that moment this benign power ceases to act. This is precisely what takes places in old and overcrowded burial grounds. Beumer, Maggiora, and others have shown that the soil of churchyards swarms with microorganisms. These are not all noxious in character, but many of them are, and the great excess of organic life is, in itself, a fact of the highest significance. The chief danger to be feared from putrefying animal matter, in or out of cemeteries, is the contamination of water supplies of individuals and cities. The intricate and extensive network of subterranean water-courses makes this a widespread though hidden danger, and one which cannot always be determined by surface indications.

It is a fatal but common error to suppose that water pollution is easily detected by the senses. Often the water most pleasing to the eye and palate is loaded with the poisonous nitrates of decomposition, and is pleasing because so contaminated.

The rôle played by microorganisms in the causation of diseases is fully recognized by modern medicine. This discovery in its importance to the race ranks among the greatest achievements of history, and fully justifies the Utopian hope that when man is wise unto his knowledge, and prepared to deal seriously with his diseases, many, if not the majority of them, will disappear.

The researches of Koch, Pasteur, Prudden, Sternberg, and other distinguished bacteriologists prove that the germ of typhoid, cholera, smallpox, diphtheria, yellow fever, and kindred diseases are, under favorable circumstances, capable of indefinite development and propagation outside the living human body. The longevity of disease germs in the soil has not been fully worked out, and depends upon conditions which must vary greatly.

For illustration let us take typhoid fever, one of the most widely distributed and most fatal of the infectious diseases. The living germ—the bacillus of Eberth—has been found in the bodies of men dead from typhoid fever three months after death (Vaughn). Robertson planted colonies of these germs eighteen inches below the surface, over which the soil and turf were carefully replaced. A year afterward, soil taken from infected localities yielded, under proper manipulation, an abundant crop of bacilli. This finding is fully sustained by the hospital records in the late Spanish-American war, in which healthy troops repeatedly and promptly developed typhoid disease, after occupying sites vacated by infected commands. Prudden found the typhoid bacillus active after having been imbedded in ice for 100 days, and Sternberg cultivated it during the greater part of a year at a

depth of nine feet below the surface. Fraenkel and Simonds found it growing luxuriantly in the spleen after death.

Similar results have been obtained from experimentation with other pathogenic germs, notably the cholera spirillum. It resists repeated freezing and thawing, multiplies abundantly in foul water, and in the contents of the intestines after death and in the soil to a depth of from three to nine feet.

Baron Seebach, the Saxon minister to France, noticed that clover had been stolen from an enclosure on his estate which was used as a burial place for animals dying of anthrax, a disease which, in Europe, annually destroys thousands of sheep and cattle. A few days later a peasant woman acknowledged the theft and stated that her cow sickened and her goat died after eating the clover. At the request of the Baron, Pasteur investigated and found anthrax germs in abundance over the graves of the sheep. Recalling the remarkable observations of Darwin as to the part played by the earthworm in bringing rolls of earth from considerable depths and depositing them upon the surface, Pasteur examined the intestinal contents of worms taken from the infected spot, found anthrax germs and reproduced the disease by inoculation in healthy sheep. Thus we have a perfect demonstration, not only of the presence of the splenic fever germs in the clover, but also of the manner in which these germs reached the surface from the bodies of the buried sheep.

The danger that may come from a single center of infection is strikingly illustrated by the unhappy experience of Plymouth, Pa. During the winter of 1884-85, owing to the freezing of the mountain stream from which the water supply was usually drawn, it became necessary to connect with the Susquehanna. About this time an imported case of typhoid fever was cared for in a house by the side of the brook. The non-disinfected excreta were carelessly thrown on the snow of a side hill. Near the end of March the melted snow, with its mass of typhoid germs, was swept into the stream. The river was now shut off and the mains filled from the brook. In this way the poisonous germs reached every part of the city, and in a short time there were over 1,200 cases of typhoid fever out of a population of 8,000 inhabitants, with a mortality rate of 10 per cent.

The time required for the destruction of the softer tissues of the bodies committed to earth varies largely with local conditions of soil and interment. Assuming, however, ten years to be a fair average, and placing the annual mortality of Greater New York at 70,000, we have continuously, in the Long Island cemeteries, not less than 700,000 bodies in various stages of decay, polluting the earth and adding to the hidden foes of those who follow after. Sir Henry Thompson writes: "By the act of interment we literally sow broadcast through the land innumerable seeds of pestilence, germs which long retain their vitality, many of them destined at some time to fructify in premature death and ruined health for thousands." By what moral right do we make the earth a storehouse of corruption? We, the living, do not hold the earth in fee; at best, we are only life tenants and are under moral obligations to pass it to our successors as pure as it came to us.

The fact, that the sooner a decaying body is disposed of the better, is as incontrovertible as death itself, and it is certainly a logical deduction that that method of disposal should be selected which is attended with the least danger. In the light of modern science there is no way in which this can be done so quickly and effectually as by incineration.

The only objection urged against incineration, on other than sentimental grounds, is that it destroys the evidences of crime, and may be used to defeat justice. This danger, slight as it is, does exist, and should lead to the utmost caution.

On the other hand, serious medicolegal complications may come from the present practice of so-called embalming. This process ordinarily consists in the useless and unscientific flooding of the cavities of the body with a preservative fluid which contains in solution nearly all of the mineral poisons known in toxicology. Thus are voluntarily and largely introduced into the body the identical and only poisons which could be detected by an analysis after exhumation. He would be a bold chemist, who would swear "beyond a reasonable doubt" that the poison in his test-tube was of ante-mortem or post-mortem introduction. The ease with which an ignorant or careless undertaker may be made to serve the purpose of the poison fiend is appalling, and suggests the necessity for better legislative safeguards than now exist.

The subsidiary advantages which would come from urn-burial are by no means few or unimportant. First, it would remove or lessen that morbid fear of premature burial which dominates the public mind to an extent little appreciated by most of us. It is idle to say that these fears are groundless, or that the sensational stories in the public prints are the cruelest of frauds; the conviction that such a calamity is possible will always be a source of dread and remorse to many.

In Frankfort, Munich, and in some of the Continental hospitals the recent dead are placed in an open room with bell wires attached to their fingers, so that the least movement would summon an attendant. These bells have never been rung. However, should trance unfortunately be mistaken for death, incineration offers in an instantaneous end, the happiest possible correction.

It may be of interest to state that the first incineration in this country, 1792, was the outcome of an imminent burial alive. The young daughter of Colonel Laurens, of whom mention has been made, apparently died and was prepared for burial. As she lay shrouded in her coffin, before an open window, the breezes from off Charleston harbor fanned into life the spark so nearly extinguished. A slight movement arrested the attention of the watchers. The family were hastily summoned and measures taken for her resuscitation. She reached womanhood and married Dr. Ramsay the patriot and historian. Laurens, upon whom the tragic episode made a deep impression, provided in his will for the cremation of his body, declaring that he could conceive of nothing more horrible than regaining consciousness in the grave.

Second, it would lessen the cost of burial, a matter of no little importance to many. The widow's mite too often melts away under the warmth of misguided affection or the imperious demands of spectacular funeral fashion. The charges at the several crematories in the United States range from $25 to $60. "Compared with inhumation," says Rev. Chadwick, "the cost need not be more than one dollar for three." The cost of earth-burial, too, must necessarily increase. The growth of cities naturally crowds the cemeteries farther and farther beyond the suburbs, and the cost of reaching them becomes, in the end, a serious tax. In the search for an appropriate resting-place, Paris carries her dead sixteen miles by a special railway. None but the

favored can sleep in celebrated Père la Chaise, in which the ground has reached a price per foot rarely surpassed in the most fashionable quarters of Paris. Then, again, incineration is a great boon to those who die far from home, but wish their ashes to lie in familiar ground.

Third, it would guarantee greater security to our remains. We speak of the grave as a perpetual home. *Vanitas vanitatum!* How many are the poor Yoricks who are "knocked about the mazzard with a sexton's spade," and yet they were consigned by loving hands to the house which was "to last till doomsday." The march of improvement does not halt at the grave. Many cemeteries have succumbed to civic needs, and the arms of a busy industry are fast stretching around and beyond their beautiful borders.

The well-known epitaph, almost a malediction, in the little church-yard on the banks of the Avon, gives expression to the fear that has haunted the dying hours of many besides the immortal bard who penned it.

"Grave-stones tell the truth scarce forty years," says quaint old Dr. Brown. Oliver Wendell Holmes writes, "Epitaphs were never famous for truth, but the old reproach 'Here lies,' never had such a wholesale illustration as in these outraged burial places, where the stone does lie above, but the bones do not lie beneath."

Fourth, it would do away with exposure at the grave. Interment necessarily takes place in the open air, and leads to exposure in all kinds of weather. This, too, when one's powers of resistance are weakened by prolonged nursing, broken rest, and the mental and physical depression which comes from breaking the tenderest of human ties.

The adoption of urn-burial would not necessarily carry with it a radical change from the present conventional mode of conducting the last obsequies nor detract in the least from the reverence accorded through centuries of civilization to the dead. The church or home service, the cortege, the rites at the sepulchre, if the ashes are returned to earth, as they should be, are equally appropriate to either mode of interment. It is, however, a decided gain to be able to select the time and weather for ministrations at the grave, thus securing proper respect for the health of the living as well as for the memory of the dead.

Fifth, it would restore to cultivation and the tax duplicate immense tracts of land. It was Plato, I think, who so vigorously protested against burial in fields fit for cultivation. Dr. Poore estimates that fifty acres would barely suffice to bury the dead of London for a single year, one in each grave. There are, in the vicinity of New York, over four thousand acres with an enormous taxable value, already given over to the use of the dead (Cobb).

The late Bishop Manchester, in consecrating a new cemetery said: "Here is another hundred acres of land withdrawn from the food-producing area of this country forever. . . . I hold that the earth was not made for the dead but for the living." With the adoption of urn-burial, a nominal acreage would suffice for the "silent cities," and thus thousands of acres would be free for the production of food, or in thickly populated districts, for breathing-spaces to promote and maintain public health and happiness.

It cannot be too strongly emphasized that incineration has nothing to do with religious doctrines or Christian faiths. It is a question of sentiment and sanitation, not of creeds or doctrines. The church, as an organization, is no longer hostile. The warmest supporters of the reform come from the ranks of the clergy, many of whom have sealed their faith by committing their bodies to the flames. Centuries ago, one of the greatest Greek philosophers said: "You may bury my body if you think not that you are burying Socrates."

If there is a better mode of disposing of the dead than the one now in vogue; one free from harm to the living, and more in keeping with advanced thought, it is plainly the duty of those having these matters in charge, not only to provide the means, but to use their influence for its adoption.

Perhaps no radical change from the conventional notions which now obtain on the subject of burial can be hoped for in the near future, and yet it seems inevitable that a reform, so strongly enforced by sanitary and sentimental considerations for both the quick and the dead, will continue to grow in popular esteem.

## HYDROTHERAPY IN THE TREATMENT OF CHRONIC DISEASES.*

By FREDERICK M. ROSSITER, B.S., M.D.,
EVANSTON, ILL.

THIS paper must necessarily be confined to the general considerations of hydrotherapy in its application to chronic diseases inasmuch as a detailed account of one of the many hydriatic procedures which may be used in the treatment of chronic diseases would consume all the time allotted to this subject.

The use of water as a remedial agent in the treatment of disease antedates that of any other remedy known to science. All the drugs of the pharmacopœa in use to-day and most of our therapeutic methods are very modern as compared to this ancient remedy. While the most ardent enthusiast of hydrotherapy does not claim that water is a panacea for all the ills that the flesh is heir to, nevertheless a close study of its many effects and reaction upon the human organism must convince one that it more nearly approaches to being a sovereign remedy than any other therapeutic agent.

Water is the most universal element found in nature, it is always to be found near at hand, it is inexpensive, it can be used successfully in the treatment of more diseases than any other remedy, and no known drug is capable of producing so great a variety of physiological effects as can be obtained by means of this limpid element.

For hundreds of years water was used empirically, and too often was principally in the hands of the laity and charlatans. Because of the unskilful use of this powerful agent, and the disastrous results that frequently followed its application, much odium was brought upon the use of water in the treatment of disease. During the past century, however, there were many pioneers in hydrotherapy who did much to place it on a scientific basis. To Winternitz, more than to any other investigator, must be given the credit of having placed hydrotherapy upon a thoroughly rational and scientific foundation by means of his classical experiments and accurate data. Along with him much credit must be given to Kellogg, Baruch, Brand, Bouchard, and Ziemssen, for having exalted the use of water into a science that can be applied to-day with more accuracy than any other physiologic method.

Hydrotherapy has its home in Germany and Austria, and a perusal of medical literature will quickly convince one that it is employed much more extensively by German physicians than it is in this country.

A large majority of the American profession, as

*Read before the Evanston Branch of the Chicago Medical Society, May 28, 1903.

well as the laity, are still afflicted with hydrophobia, due principally to water being used empirically and unscientifically, and hence the unsatisfactory results; for it must be borne in mind that so powerful an agent as water, like a powerful drug, if unskilfully used, is capable of producing much harm.

There are doubtless several reasons why hydrotherapy is no more extensively used by physicians to-day than it is, in the treatment of both acute and chronic diseases. In the first place the subject is barely mentioned in the medical schools, and only in one or two medical schools does it have a place in the curriculum. Hence, for a physician to acquire a knowledge of the subject he must either study it up and perform many experiments, or take a post-graduate course, which necessitates a trip abroad as there is no efficient hydriatic clinic in this country. Second, the extensive employment of hydrotherapy, whether in private practice or in institutions, requires a trained nurse, and there are few trained nurses prepared to give a skilful hydriatic treatment, because of the lack of tráining. Nurses after graduating frequently have to be given special training before they are qualified to give even some of the more simple hydriatic treatments. The results which a physician expects to obtain may be entirely frustrated by a poorly given treatment. Proper education will remove both of these objections to the more common employment of hydrotherapy in the practice of medicine.

In order to be able to use water scientifically it is absolutely necessary to have a thorough knowledge of anatomy and physiology. Especially is it important to know the anatomy of the nervous and circulatory systems and of the skin. The fifteen to seventeen square feet of skin that covers the average adult is a highly sentient organ, intimately related to the central nervous system through the millions of nerve endings represented among its epithelial cells. It is principally through this sensitive organ that the hydriatist produces the desired physiological action in the cure of disease. The skin is to him what the cords are to the harpist. It is a vast reflex area in which are represented every organ, and gland and muscle. As a rule every organ is in reflex relation with the skin immediately over it, however many organs are in addition, in reflex relation with remote portions of the skin. For instance, the palms of the hands are in reflex relation with the mucous membrane of the nose and with the brain; the plantar surfaces are in relation with the bladder and the uterus, the integument over the lower third of the sternum with the kidneys, et cetra. Possessed with a knowledge of all the reflex areas of the skin, one can obtain a local or general effect at will in the use of hydriatic procedures, a fact which is highly important in the treatment of various diseases.

It is well known that washing the face with cold water is wonderfully refreshing and restful. The cold to the face excites the nerve endings of the trifacial, which in turn reflexly contracts the cerebral blood vessels and increases the venous flow from the brain. Then again it is well recognized among women that the catamenial flow may be suddenly checked by cold wet feet.

Now it logically follows, that if one may be so refreshed by simply bathing the face with cold water, a much greater effect can be obtained by a proper general application, and if this is repeated daily, marked physiological changes may be wrought in the body. This is a principle that applies to every hydriatic procedure, whether local or general in application.

Water not only makes up 66 per cent. of the total weight of the body, and forms a part of every tissue, but it is also a convenient means of exciting the nerve centers, of communicating heat to the body, and of promoting a loss of heat from its surface. Upon these facts depends its physiological action.

Any application to the body at the temperature of the skin is neutral in effect, and hence is neither exciting nor depressing. Any application with a temperature above that of the skin is interpreted as warm or hot, and any application below the skin temperature is recognized as tepid, cool, or cold. Extremes of heat and cold cannot be differentiated by the nerve endings and hence the effect is the same. In individuals unaccustomed to hot or cold applications and in certain diseases the skin has to be educated to variations in heat and cold. In hyperæsthesia of the skin in locomotor ataxia this is especially noticeable.

The physiological effects which we wish to obtain from a certain treatment will depend upon whether heat or cold is employed, the degree of each, the force, if it be a douche, and the duration. Most of the physiological effects of hydriatic treatments are due to so-called reactions and to the mechanical influence upon the blood and lymph.

The following are some of the hydriatic procedures used in the treatment of acute and chronic disease: the shower, the spray, hot or cold; the douche, hot or cold, alternating, and percussion; local or general, named according to area treated; the Brand bath, Bouchard bath, or graduated bath, the neutral bath, half-bath, hip or sitz bath, leg bath, foot bath, arm or hand bath; simple sponging, friction, towel rubs, wet sheet rubs, pail-pour, hot or cold compresses, named according to location, alternating compresses, evaporating and non-evaporating compresses, the moist girdle, fomentations, the dry blanket pack, the wet blanket pack, trunk pack, chest pack, hip and pelvic pack, leg pack, wet sheet pack, enemas and effusions. All of these treatments are applicable to the home excepting the Brand bath, the graduated bath, the sprays, and the douches.

By the employment of one or more of these measures or combinations the following effects may be obtained: tonic, local or general, sedation, antispasmodic, nutritive, eliminative, diuretic, expectorant, antipyretic, antiphlogistic, hæmostatic, emmenagogic, analgesic, vasodilator, vasoconstrictor, and hypnotic.

Gastrointestinal diseases with a chronic tendency, and with their multitudinous local and general manifestations, furnish no inconsiderable proportion of the chronic diseases with which the physician has to deal. It is in the treatment of these diseases that the so-called water cures and hydriatic institutions of Germany and Austria have become popular.

In the treatment of the varied forms of dyspepsia hydrotherapy is by no means an exclusive treatment. The most careful consideration must be given to dietetics, exercise, electricity, and personal hygiene. In chronic gastritis and enteritis we have more to deal with than the local manifestations. We find a general lowering of vital resistance, local anæmias, vasomotor disturbances, inactive emunctories, toxæmia, exhausted nerve centers, and even marked mental phenomena.

In treating gastritis it is highly important to know the state of peptic activity, whether there is hyperchlorhydria, or hypopepsia. Long ago Dr. Beaumont showed that cold water taken into the stomach during peptic activity inhibited temporarily the flow of gastric juice. On the other hand Professor Pavlov of St. Petersburg in his recent experiments

upon the digestive function shows that cold water taken before meals excites a flow of gastric juice. Moreover, he shows by repeated experiments that the so-called stomachics and bitters, and carbonates introduced into the stomach before meals do not cause a flow of gastric juice. Aside from the psychic influence, the flow of gastric juice is greatly determined by the quantity and quality of blood in the walls of the stomach.

The ice-bag or cold compresses applied to the epigastrium half an hour before meals will increase the arterial flow in the walls of the stomach, and hence the flow of the gastric juice. Prolonged hot applications over the stomach after meals will diminish the flow of gastric juice, and likewise will a general application of heat to the skin by diverting the flood from the stomach into the periphery. Drinking hot water or brief fomentations to the epigastrium after meals will relieve pain due to fermentation or hyperacidity. Likewise a hot leg pack, together with a cold compress over the abdomen and hot and cold to the liver, will relieve an over-charged portal system and increase the arterial flow. In malnutrition it is very interesting to observe what changes will be wrought by so simple a measure as hot and cold to the liver and to the spine daily, and a general cold friction.

The cold friction is a powerful tonic to the circulation, glandular activity, and to the nervous system. A blood count, following an application of cold, will show a great increase in the number of blood cells. Not that they are manufactured by the treatment, but they are forced out of the deep-seated organs and congested areas into the general circulation. In a case reported by Winternitz the blood count was increased 1,800,000, per c.c. by a hot bath followed by cold. It is obvious that any measure that will put into commission so many more working blood elements, and stimulate glandular, and hence metabolic changes, must materially aid in restoring the physiological forces of the body to the normal.

Among other hydriatic procedures to be used in treating digestive disorders because of their nutritive and tonic effect, is the cold towel rub, the wet sheet rub, and the pail-pour. The most powerful hydriatic effects are to be obtained by means of the douche. For constipation which is exceedingly common in gastrointestinal diseases, the wet girdle is one of the most effective measures.

In the treatment of organic heart diseases hydrotherapy has given the most gratifying results. Dr. Schott of Nauheim, who has made the effervescent baths so popular in the treatment of dilatation of the heart, claims that he has even caused cardiac murmurs to disappear under this treatment. The artificial Schott treatment is just as effective as those given at Nauheim. The physiological action of this bath depends entirely upon the stimulation of the nerve endings by the carbonic acid gas held in the water. This treatment can be given in any home where there is a proper sized bath tub.

While extremes of general heat and cold are contraindicated in organic heart disease, most excellent results can be obtained from milder and local applications. The ice-bag or cold compresses applied over the heart caused a material reduction in size of the organ, and diminished the number of contractions as well as increasing the efficiency of each. In mitral insufficiency with failure of compensation, attended by œdema so marked that the patient could hardly move in bed, I have seen the œdema entirely disappear in two weeks' time by the use of the ice-bag and general cold friction three times a day.

Some time ago a patient consulted me for insomnia and a headache that came on about one or two o'clock in the morning, making sleep impossible. This symptom had been present for two months. On examination, among other conditions, I found dilatation of the heart, a pulse between 90 and 100, and an atonic condition of the blood vessels. For these symptoms I ordered the ice-bag over the heart at bed time, with a general cold friction treatment. In one week the headaches entirely disappeared and the patient could sleep all night.

We occasionally meet with patients who have an insufficient blood supply, and who have the greatest difficulty to keep awake during the day time, but as soon as they lie down at night they are wide awake and cannot go to sleep. Gravity keeps the brain in a state of anæmia while in the upright position, a condition favorable to sleep, but as soon as they assume the horizontal position the blood rushes back to the brain and sleep takes its flight. In these cases there is a marked atonic condition of the blood vessels. I have found that the ice-bag applied to the præcordium at bedtime, together with a cold friction, will almost invariably give the patient immediate sleep.

In chronic nephritis there are many clinical indications that are well met by hydrotherapy. With a high blood-pressure, due to arteriosclerosis, a throbbing head and great irritability of the skin rendering sleep impossible, a prolonged neutral bath at bedtime is one of the most efficient sedative measures in giving comfort to the patient and making sleep possible.

Insomnia, a symptom common to many of the functional and organic diseases, yields very readily to hydriatic measures without resorting to depressing drugs. The neutral bath, the neutral-electric bath, large fomentations to the spine, the wet sheet pack prolonged for an hour or more without inducing perspiration, are all effective treatments in promoting sleep.

Probably more can be done for chronic functional disorders by hydriatic treatment than by the use of any other one measure. In nearly all these cases the patient requires constitutional treatment along with the local measures. For pelvic pains nothing gives the patient more relief and comfort than the hot hip pack and the hot sitz bath. The alternating hot and cold hip pack is a most excellent local tonic measure. In amenorrhœa, in addition to removing the cause if possible, and general tonic treatment, I give the hot hip pack, the hot leg bath, and warm douches, together with electricity. When heat is used for menorrhagia and metrorrhagia it should be used at the highest point of toleration and of brief duration. Prolonged cold gives more satisfactory results.

Rheumatism, diabetes, neurasthenia, nervous diseases, incipient tuberculosis, chronic malarial poisoning, and many other diseases that might be mentioned, when treated scientifically with hydrotherapy, give results that justify the more extensive use of this therapeutic measure.

---

**The Ear a Manometer.**—In a note entitled "The Ear a Manometer," M. Pierre Bounier sets forth a new theory of hearing, to wit, that the liquid of the internal ear moves as a whole, so that audition is a hydrodynamic, not an acoustic, phenomenon. The ear is not a resonator, but a registering manometer, in which variations of pressure are alone recorded. He points out that the nerve of the labyrinth is thus brought under the common law of the apparatus of sensation.—*Scientific American.*

## THE SUPRAPUBIC OPERATION FOR THE RADICAL CURE OF VARICOCELE, WITH A REPORT OF EIGHTEEN CASES.

By ROBERT M. THORNBURGH, M.D.,
FIRST LIEUTENANT MEDICAL DEPARTMENT, U. S. ARMY.

On February 27, 1901, a circular, from the office of the Surgeon-General of the Army, invited the attention of the officers of the Medical Corps to the suprapubic method of operating for the radical cure of varicocele.

Sixteen cases were reported by Col. A. C. Girard, sixteen by Major J. M. Banister, nine by Major W. C. Borden and three by Major A. E. Bradley. It was stated that General Forwood had also employed this method when stationed at the Soldier's Home.

The writer has had the opportunity to examine over 4,500 recruits at Fort Slocum, N. Y.—a recruiting rendezvous—and has thus been able to pick a number of cases for operation. The rule laid down in "Tripler's Manual" has been followed, *i. e.* operate upon those cases in which the varicocele is as large or larger than the sound testis. Eighteen men were found to come within this rule and were operated upon by the suprapubic method. Some four or five cases, previous to June, 1902, were operated upon by the open scrotal incision, with good results in all but one case. In this a sinus persisted, requiring three subsequent operations before the patient could be returned to duty.

The suprapubic route seems by all means to be the better. The field of operation can be more readily rendered aseptic; a dressing once properly applied will remain indefinitely and not be affected by the movements of the patient; and primary union is a practical certainty. It would appear to the writer that there are no advantages whatever that can be urged in favor of the scrotal incision.

With very slight modification, the technique employed by Colonel Girard has been followed by the writer.

The morning before operation the patient is bathed, put to bed, the pubes shaved and scrubbed with tr. green soap and water, followed by rinsing with ether. A nurse, with sterile hands, now rubs in four grams of oleate of mercury over a space completely covering the field of operation. A sterile gauze dressing is saturated with oleate of mercury, applied to the skin and bandaged in place, first covering dressing with oiled silk. (This inunction with the oleate, for the prevention of stitch abscess, is described by Maylard of Glasgow, in *Annals of Surgery*, for January, 1902.)

The patient is given a dose of salts, which is followed by a soap-suds enema at 6 A.M. next day. No breakfast, nor even water, allowed after 6 A.M. The urine is tested for albumin and sugar and the heart and lungs carefully examined. Should all be normal, anæsthesia is commenced at 9 A.M. Chloroform is used to full surgical narcosis and then ether is substituted. No untoward results have followed this practice, the patient usually reviving within fifteen or twenty minutes after withdrawal of anæsthetic, and so much less anæsthetic is required, than when ether alone is used, that no subsequent vomiting has occurred. It is also worthy of note that no morphine has been required for pain, nor has any hypnotic been needed.

When the anæstetized patient is brought into the operating-room, the dressing is removed and an assistant re-scrubs the field with tr. green soap and water; ether is poured over and rubbed in, followed by alcohol—about 30 c.c. of each. A one-per-cent. solution bichloride is now poured over the field. The finger of the operator is introduced into the external ring and a nick made with the knife directly over the tip of the finger. With this nick as a landmark an incision 3 cm long is made, parallel to Poupart's ligament. The deep fascia is cut through with the knife, and then a little blunt dissection brings the cord into view. No blood vessels of any moment are encountered; oozing being checked by hot normal salt-solution. The sheath of the cord is picked up between mouse-tooth forceps and torn open. The finger of the operator is introduced and the whole cord easily raised from its bed and brought out of the wound; a ligature carrier is then placed beneath it. The vas is recognized by its white appearance and cord-like feel and is separated from the rest of the cord downward to within an inch of the testis. The testis can readily be brought into view by gentle traction on the cord. The vas is separated from the vessels for about 6 or 7 cm. in an upward direction also. The vessels are tied with No. 3 cumolized catgut ligatures, the vessels between them (5 to 6 cm.) excised, the stumps inspected for oozing, the ends approximated and the ligatures tied to each other; thus forming a support for the testis.

(In the opinion of the writer it is unnecessary to isolate and save the spermatic artery and a vein. This was formerly done, but has been abandoned with equally excellent results.)

The cord and vas are dropped into the bottom of the wound and the wound closed by continuous retention and approximation sutures. No. 1 cumolized catgut being employed.

The wound is covered with two or three thicknesses of naphthalin gauze, then ten or twelve thicknesses of plain sterile gauze, and this held in place by adhesive straps. A two-inch thickness of absorbent cotton placed on top and the whole held in place by a spica bandage.

At the end of twelve days (unless pus be indicated) the dressing is removed and the suture found absorbed. A little collodion is painted on the line of incision, the patient allowed up and returned to duty in three or four days, *i. e.* as soon as there is no tenderness on palpitating cord and testis. The patient is given a suspensory bandage immediately after operation and told to wear it six weeks. Usually, however, it is only worn when the patient is in hospital.

In closing, it may be well to give the method of hand sterilization employed at this hospital, since its results have been very satisfactory.

After paring and cleaning the nails, the hot water faucet is turned on and the hands and forearms thoroughly scrubbed for five minutes in tincture of green soap and rinsed with the hot running water. All brushes have been sterilized and each person uses an individual brush in each scrubbing operation. After rinsing, about 10 gms. each of chloride of lime and sodium bicarbonate are put in the palms of the hands and *cold* running water allowed to drip on them. A considerable amount of chlorin is evolved, which thoroughly disinfects the hands. This mixture is rubbed into the skin of hands and forearms, with a brush, for two or three minutes; the arms and hands rinsed in cold running water and then soaked five minutes in a 1 per cent. bichloride solution; from there to a 5 per cent. creolin emulsion for three minutes and the hands are considered sterile. A 1 per cent. trikresol solution is used to dip the hands in during operation.

The only objections to this method are: the irritating effect of the chlorin on the eyes and nasal mucous membrane and the causation of a slight dermatitis if used more than once a day. The writer has, however, cleaned his hands in this manner three or four days in succession without experiencing

sufficient skin irritation to cause inconvenience. For the surgeon operating several times daily for a number of successive days it might, perhaps, prove impracticable.

In every case thus far treated, primary union took place, and in one only did a drop of pus appear. A cure has resulted in every case.

In case 14 a stitch abscess occurred which necessitated opening the incision, draining, and allowing to heal by granulation. A 5 per cent. argyrol solution was used effectively.

In case 16 there was a slight epididymitis and hardness of the cord one month after operation. This was probably due to the fact that it was necessary to use chromicized gut, as none other was on hand at that time. This gut being so slowly absorbed may have produced irritation mechanically through movements of the body.

Since writing this report the operation has been done by the writer on fifteen more cases with perfectly favorable results in each case.

Case I.—M. D., recruit, age twenty-one years, white; nativity, New York, two weeks' service. Admitted, June 17, 1902. Varicocele, left, large. Operation June 27. Technique as described above. Primary union. Returned to duty, cured, July 10.

Case II.—K. J. T., recruit, aged twenty-three years, white; nativity, Ireland; three weeks' service. Admitted, June 27, 1902. Varicocele, moderate, left. Operation, July 1. Primary union. Duty, cured, July 16.

Case III.—W. D., recruit, aged twenty-one years, white; nativity, New York; one week's service. Admitted, July 4, 1902. Varicocele, large, left. Operation, July 9. Primary union. Duty, cured, July 26.

Case IV.—K. P. J., recruit, aged twenty-one years, white; nativity, Pennsylvania; two weeks' service. Admitted June 23, 1902. Varicocele, moderate, left. On testing urine considerable albumin found. Patient sent to medical ward for treatment. Had not other symptoms of nephritis. Albumin not found after July 16. Operation, July 20. Chloroform used entirely. No albumin found after operation except a trace on July 24. Primary union. Duty, cured, August 7.

Case V.—G. E. T., recruit, aged twenty-six years, white; nativity, Tennessee; one week's service. Varicocele, very large (larger than fist), left. Admitted, July 16, 1902. Operation, July 22. Primary union. Duty, cured, August 7.

Case VI.—N. C., recruit, aged twenty-two years, white; nativity, West Virginia; one month's service. Admitted July 29, 1902. Varicocele, large, left. Operation, August 5. Primary union. Duty, cured, August 18.

Case VII.—W. E., recruit, aged twenty-four years, white; nativity, Virginia; one week's service. Admitted July 29, 1902. Varicocele, moderate, left. Operation, August 5. Primary union. Duty, cured, August 18.

Case VIII.—V. O., recruit, aged twenty-two years, white; nativity, Maine; two weeks' service. Admitted August 13, 1902. Varicocele, large, left. Operation, August 24. Primary union. Duty, cured, September 9.

Case IX.—D. J., recruit, aged twenty-one years, white; nativity, West Virginia; one week's service. Admitted August 22, 1902. Varicocele, moderate, left. Operation, August 29. Primary union. Duty, cured, September 15.

Case X.—I. J. M., recruit, aged twenty-one years, white; nativity, Tennessee; one week's service. Admitted August 22, 1902. Varicocele, large, left. Operation, September 1. Primary union. Duty, cured, September 15.

Case XI.—R. W., recruit, aged twenty-three years, white; nativity, New Jersey; one month's service. Admitted October 20, 1902. Varicocele, large, left. Operation, October 28. Primary union. Duty, cured, November 15.

Case XII.—F. J., recruit, aged twenty-four years, white; nativity, Massachusetts; two weeks' service. Admitted January 28, 1903. Varicocele, large, left. Operation, February 6. Kangaroo tendon used for ligatures and sutures, no catgut being on hand at time. Dressed February 15. Sutures entirely *absorbed*. Primary union. Duty, cured, February 23. Patient did not wear suspensory as ordered and slight epididymitis ensued, which disappeared before patient was returned to duty.

Case XIII.—B. W. G., recruit, aged twenty-three years, white; nativity, New York; one month's service. Admitted January 28, 1903. Varicocele, large, left. Operation, February 6. Kangaroo ligatures and sutures. Primary union. Duty, cured February 19.

Case XIV.—G. G. H., recruit, aged twenty-one years, white; nativity, Massachusetts; one month's service. Admitted February 14, 1903. Varicocele, moderate, left. Operation, February 16. Kangaroo ligatures and sutures. Suture evidently not sterile. Stitch-abscess appeared and had to be opened and allowed to heal by granulation. Duty, cured, April 12.

Case XV.—R. T., recruit, aged twenty-one years, white; nativity, Massachusetts; three weeks' service. Admitted February 16, 1903. Varicocele, moderate, left. Operation, February 18. Kangaroo ligatures, chromicized gut sutures. Sutures removed March 1. Primary union. Duty, cured, March 4.

Case XVI.—P. C., recruit, aged twenty-three years, white; nativity, West Virginia; three weeks' service. Admitted February 16, 1903. Varicocele, large, left. Operation, February 19. chromicized gut ligatures and sutures. Sutures removed March 1. Duty, cured, March 5. Soldier was sent to Fort Williams, Me. Surgeon at that post informs the writer that a slight epididymitis, with hardening of the cord, had developed about April 1. No later information.

Case XVII.—L. A., recruit, aged twenty-one years, white; nativity, New Hampshire; three weeks' service. Admitted February 17, 1903. Varicocele, moderate, left. Operation, February 19. Chromocized gut ligature; kangaroo sutures. Suture absorbed March 1. Primary union. Duty, cured, March 1.

Case XVIII.—B. B., recruit, aged twenty-seven years, white; nativity, New York; twenty-five months' service. Admitted February 20, 1903. Varicocele, moderate, left. Operation, February 23. Cumolized catgut on hand and used for this and subsequent operations. Primary union. Duty, cured, March 9.

The writer desires to express his sincere thanks for the valuable advice and assistance rendered by the post-surgeon, Major H. S. T. Harris, U. S. A.

Fort Slocum, N. Y.

---

**The Causes and Prognosis of Sudden Blindness.**—George W. Benschoten gives the following causes of this affliction: (1) Embolism of the central artery of the retina, or thrombosis of the vein; (2) apoplexæ retinæ, or hemorrhage into the retina, including also the vitreous; (3) excessive hemorrhages from the general circulation; (4) uræmia; (5) spasm of the retinal vessels or ischæmia of the retina; (6) detachment of the retina, or a

sudden increase in detachment of an already loosened retina; (7) hysteria; (8) acute infectious diseases (rare); (9) disseminated sclerosis, also rare. As can be judged from the foregoing, it requires a close examination of the heart and circulatory system and of the urine to arrive at the probable indirect cause in many of the cases. Much can often be done by treatment, but for a rational application of the same a correct diagnosis of the condition present must first be made. It is well to remember that the statements of patients are often unintentionally misleading. They may claim a sudden loss of sight in one eye when they first discover the blindness, but the vision may have gradually been failing for some time, the patient being totally unaware of the fact; again the statement that the sight is absolutely gone in one eye may be made, when upon close questioning and examination they admit that vision may still be present to a greater or less degree, but so poor as to lead them to claim a full loss.—*The Providence Medical Journal.*

**A New Retroflexion Operation.**—S. A. Alexandroff suggests anterior approximation of the bases of the broad ligaments for the purpose of elevating the cervix, and, by holding it backward, throwing the body of the uterus forward. The operation is done as follows: Retractors are placed in the vagina and the cervix is pulled down. A semi-circular incision with the concavity upward is made in the anterior vault, and this flap, together with the bladder, is stripped back as high as possible. A traction suture is placed in the base of each broad ligament 3 to 3½ cm. from the uterus by hooking the finger under the lower edge of the ligament and pulling it forward so that the ligature can be passed through a firm mass of tissue about 1 cm. thick. The uterus is now placed in anterior position by bimanual manipulation, and traction in the cervix stopped. The two traction ligatures are crossed and pulled upon by the assistant so as to bring together in front of the cervix the two portions of the base of the broad ligament they pierce. These two stout strands of tissue are united by sutures which also penetrate the substance of the cervix. The internal os forms the upper limit of the suture. The incision in the fornix is then closed by suture. The author has been able in all cases to correct the prolapse and restore the uterus to its normal position without impairing in any way its motility or causing circulatory or menstrual disturbance. No danger to the ureters is to be apprehended if the operation is done as described.—*Centralblatt für Gynäkologie.*

**Laparotomy Convalescence, with Reports of Twenty Illustrative Cases.**—Robert Wallace Hardon says that the large percentage of cases operated on by him during the last four years have been allowed to get out of bed in from one to four days following operation, and in none have any but the best results been seen. Marked increase in the comfort of the patient in every way was noted following this line of procedure. Patients left the hospital stronger, and were sooner able to assume their occupations than had been observed to be the case when kept in bed for a much longer time. The additional comfort of the patient comes from being able to have more complete bowel movements, consequently less flatus and distress from this often troublesome feature; from the change of position and avoidance of any bed pressure symptoms; from a less nervous condition incident to keeping them as confined as is the custom, and from an absence of muscular weakness caused by an atrophy of disuse.—*Medicine.*

**Two Cases of Lymphatism.**—George Peacock reports two cases of sudden death in apparently normal children. The post-mortem in one showed a thymus gland which almost covered the heart, and which measured in its greatest length 102 mm. and in its greatest breadth 63 mm.; its volume was 37 cubic centimeters. The mesenteric glands were universally enlarged and hard. In the second case the thymus, as in the former instance, was nearly double its normal size. Dr. Thursfield, as quoted by the author, describes four cases of sudden death in infants, associated with enlargement of the thymus gland, and thus summarizes the points in common: "The sudden death, the absence of any lesion sufficient to account for death, the presence of bulky and heavy thymus glands, and the evidence of hypertrophy of the lymphatic tissue shown in the enlargement of the Peyer's patches and the solitary follicles, and in two cases, of the lymphatic glands." Laqueur reports on cases, and Kendrat has collected twelve. The cause of death in all seems quite obscure. It has not been proved to be due to direct pressure on the trachea, or to pressure on the vagi in the neck by an enlarged thymus, nor to coagulation of the blood, the result of thymus secretion, nor to the presence of toxins in the circulation. Further investigation is needed to discover the relation existing between hypertrophia lymphoid structures and sudden death in young children.—*The Dublin Journal of Medical Science.*

**The Therapeutic Uses of the Preparations of Benzoin.**—H. R. Coston uses the compound tincture of benzoin to seal an incised wound in healthy tissue, or cracked nipples, granulating surfaces, bed-sores, chapped hands, anal fissure and the secondary periods of frost-bite. Chronic forms of eczema are benefited by painting them with the tincture of benzoin, or dusting with the benzoate of bismuth. Liver spots will be removed by the use of tr. benzoin. comp. ℥iss; hydrargyri chlor. corrosiv. ℈i; Aquæ cologniensis q. s. f. ℥viii, applied twice daily. Sore throats are much improved by the acid in solution or the tincture applied locally. The great indication for the internal use of the benzoates is ammoniacal urine. In cases of chronic cystitis the author gives 15 or 20 grains every two or four hours. For nocturnal enuresis with neutral or alkaline urine give three to five-grain doses after each of the principal meals. Headache of lithæmic origin will be cured by the use of these remedies. The benzoate of bismuth may be given with excellent results in diarrhœal troubles in children. In chronic bronchitis benzoic acid or benzoate of ammonium will be found of signal service. All forms of influenza are benefited, and if there is much arterial excitement add two or three drops of tincture gelsemium to each dose. As antiperiodics the benzoates are worthless; as antipyretics they are reliable only in so far as they exert their specific effects upon the disease for which they are given and because of the slight diaphoresis and diuresis which is caused by them.—*The Therapeutic Gazette.*

**The X-Rays in the Treatment of Rodent Ulcer.**—J. Hall-Edwards declares that in the *x*-ray treatment of rodent ulcer we have already achieved a success which must mark an epoch in the history of therapeutics. These ulcers, as a rule, tend to extend along the course or channel of the exudate. In one of the cases reported by the writer the ulcer had invaded the orbit. The disease has made no progress during the time (sixteen months) the case has been under treatment, but without surgical interference no cure can be looked for. The condition of the patient is at the present time far more satisfactory than it has been for years. He is practically free from pain, has no hemorrhage, and his general condition is better than it has been for more than thirty years. A few applications of the rays are given occasionally, no other treatment being adopted. Several cases of rodent ulcer involving the inner canthus have been difficult to heal when the orifice of the lacrymal duct was included in the diseased area on account of the exudate from the ulcer washing over the eyelids and acting as a constant source of irritation. Otherwise, when the duct is not involved the rays have soon cured the disease. In cases of ulcer near the eye, every care should be taken to protect the eye from injury, at the same time the whole organ has been exposed when necessary without fear, with no ill result. In cases of rodent ulcer on the face, treated by *x*-rays, a mask of some kind must be used.—*Treatment.*

## RESPONSIBILITY FOR PROPER MILITARY SANITATION.

Two papers in the June number of the *Journal of the Association of Military Surgeons* exemplify two aspects of army medical life, and one of them shows the urgent need for fuller recognition of the surgeon as the authoritative official sanitarian. In his address to the graduating class of the Army Medical School the Secretary of War says: "The opportunities of the Medical Corps of the army are constantly widening. The policy which is now being pursued of taking care of the larger army in larger posts instead of scattering it in small posts will greatly increase your opportunities for practice, and for research and for individual growth. The large posts, where there will be the attrition among many men, association with your seniors and the opportunities that come from a great collection of men will take the place for you of those little one and two company posts in which the isolation and the lack of occupation and of opportunity led so many a promising young man to dwindle and dry up before he reached maturity.

"Congress is continually broadening in its treatment of every scientific branch of the army. It takes time and campaigns of education to secure the adoption of measures and the grants of money necessary for great steps in advance, but that kind of campaign is going on all the time, and I look with great confidence to see at an early date complete success following the efforts of your chief, the surgeon-general, to secure ample endowment for a greater army medical school and more complete hospital facilities for the members of your corps in the city of Washington."

This is the bright side. On the other hand, Surgeon-Major William O. Owen instances the contemptuous, mind-your-own-business manner in which commanding officers sometimes receive proffered advice as to sanitary matters from their medical officers, and the deplorable results that follow. At the same time Dr. Owen points out that under the present regulations—or lack of regulations—the commanding officer is strictly within his legal rights, and is accountable to no one for epidemics which may follow, and which have followed. Thus in the Crimean war, the road from the landing to the firing line was marked by the dead animals, and the camps were polluted in every possible way; regiments showed losses of from 20 to 75 per cent., and one a death loss greater than its average strength; yet a general told the medical inspector he had better keep his strictures and criticisms to himself until they were called for. In our Civil War more than 1,800,000 cases of typhoid, diarrhœa, and dysentery were reported with 80,000 deaths. Relative to the Spanish war a general testified that the opinion of his chief-surgeon had not been borne out by the water analysis, yet 9,960 men of his command contracted typhoid fever, and 714 died; a disability of over 20 per cent. If a general had deliberately led his men into an ambuscade of whose existence he had been warned by his scouts, he would be held responsible; but here when a description of his camp written by a sanitary inspector was read to him he wanted a copy so that, as a general officer, he might court-martial the writer for daring to write such a report! Also Dr. Owen cites the case of a medical officer who, since the year 1900, when he gave advice to the commanding officer to the effect that if the men were not housed in temporary quarters instead of in tents, it would result in loss of life from pneumonia, was told to "keep it to himself" until called for. Dr. Owen says that, with such conditions as this staring us in the face, it does, indeed, seem time that steps were taken looking to a correction of these evils so plainly evident from a perusal of McLeod's "History of the Crimean War," from the proceedings of the Chelsea Board on the same war, and from the published records of the Surgeon-General's office, such as the Medical and Surgical History of the War of the Rebellion, the report of Reed, Vaughan, and Shakespeare upon the "origin and spread of typhoid fever in the military camps of the assembly within the United States in 1898," together with the report of the commission appointed by the President to investigate the conduct of the War Department in the war with Spain, and the eight volumes of testimony taken before it.

The remedy Dr. Owen considers to be in the Medical Department itself. It should organize, and through its recognized head, the Surgeon-General, show to the Secretary of War, the great numbers disabled and dying from preventable diseases, that proper sanitation would largely decrease the number, that the fault lies, not with the medical men who have given advice which the generals refused to heed, that the losses occur, not in time of emergency, but in assembly, instruction, or wintering camps, and that there is a definite chain of responsibility for diseases in camp. It should show Congress that such a law would save money and lives, and that with the number of men thus placed on the firing line, the result on the moral and physical force of those on it will be better—and it will at least receive a respectful hearing; for it will be evident that the medical corps is trying to accomplish a public good and not a personal advantage. "Let the organization insist upon a law that will enforce upon the commander a direct legal personal responsibility for his refusal to allow proper sanitary precaution to be taken, leaving him always the absolute right to refuse all sanitary suggestion whenever there is in his judgment a military necessity requiring it, and allow him to be the sole judge of when and under what condition it should be done—hold him to a legal responsibility that his results are good ones, but do not leave him such a latitude as will allow him to go unpunished when he

deliberately sets at defiance all the rules recognized the world over by sanitarians, or when he by his deliberate personal example encourages his men to violate them, allowing his men to drink water which he has been advised is polluted—he may be immune from the disease, it is certain some of his men will not be. As far as I have been able to obtain the history of the Boer war in South Africa and the camps of assembly and instruction in the U. S. in 1898—they are excellent examples of the result to flow from this lack of legal responsibility before the statute law of the land. Give the general in command the proper medical advisers and compel him to take the responsibility before the law. He will then have to stop and think of the cost of human life. Leave him always free in the face of the enemy with one thought alone, 'What is the best way to defeat the purpose of the enemy of the country?' But in camps of assembly and instruction he should have this added responsibility. Do this, and no general will for a moment hesitate to insist upon the most absolute fulfilment of the rules of sanitation by the medical officers under his orders, nor, on the other hand, will he hesitate for a moment when, in his judgment, it is necessary to throw all sanitary precautions to the wind, for it is far better to lose 100 men to disease than to the battle for fear of results to flow from insanitary condition. He should then simply direct his medical officers to take such precautions as they may, under conditions over which he has no control." To this we might add the suggestion that a part of the curriculum at West Point for the senior class should be a course in military hygiene upon which army surgeons could lecture. This would result in impressing the gravity of the problems upon the future officers, and further accustom them to refer to the medical corps as the natural arbiters in matters hygienic.

## TRYPANOSOMIASIS IN HORSES AND MAN.

After the sporozoa the protozoa most likely to cause disease are the flagellata, of which the best known pathogenic genus is *Trypanosoma*. Unlike the sporozoa, which are chiefly, if not entirely, intracellular parasites, the trypanosoma appears never to enter the red blood cells. W. E. Musgrave and N. E. Williamson give, in No. 3 of the Publications of the Bureau of Government Laboratories, Manila, an account of an epidemic of trypanosomiasis of horses in the Philippines which constitutes an instructive instance in epidemiology. The authors are satisfied that trypanosomiasis did not exist in the Philippines prior to May, 1901. Previous epidemics were rinderpest; not trypanosomiasis, or surra. In May, 1901, the disease appeared among some horses imported that month from Australia, and soon spread to the cavalry horses stabled across the street, and during the next two years 5,787 army horses and mules were killed for surra and glanders. Though accurate figures are wanting, the loss among the horses of the Civil Government and private parties was also very heavy, and a conservative valuation of the direct loss would not be less than $2,000,000. The parasite, Trypanosoma, is characterized by an undulating membrane along one side of the body, and drawn out into a whip-lash, or flagellum, at one end. The genus has a bad reputation. Besides being responsible for the "surra," it produces the nearly allied nagana, or tsetse-fly disease, of horses and cattle in South Africa. The mode of transmission is said to be chiefly by means of blood-sucking insects which, obtaining the parasite when feeding upon animals having the disease, pass them on to the next animal bitten. Trypanosomiasis may also be inoculated upon a wounded surface by non-biting insects, and the "maladie de coit" has been produced by smearing the vulva of a bitch with blood containing *Trypanosoma equiperdum*. As insects only transmit surra within about forty-eight hours after the acquisition by them of the infection, it is inferred that the transmission is purely mechanical and that the insects do not act as an intermediate host in which a distinct stage of the parasite's development takes place. In Manila some of the rats were also found to harbor the same trypanosoma (*Trypanosoma evansi*) which produced the horse epidemic. As fleas have been shown to carry the infection from rat to rat, we are tentatively, and until investigation has shown exactly what insects are to be incriminated, to hold all insects as possible agents in the spread of the disease. It is probable that inoculation is the only mode of transmission. Thus after vain attempts at infecting a monkey with contaminated food, infection took place promptly after a small mechanical abrasion of the oral mucous membrane had been made. Mechanical modes of inoculation thus suggest themselves, such as the passing on of the disease by bridles, combs, or brushes to sores on another animal. In the perpetuation of the disease during the intervals between epidemics wild animals probably play the part of host for the parasite; some of these animals perhaps not suffering much from its presence. Again rats are found infected during the dry season, and may well serve through the intermedium of the fleas always numerous upon them, as standing foci for reinfection of the draught animals. But in Manila itself, at any rate, even in the dry season there are always enough sick horses driven along the streets and enough flies to explain reinfection.

The existence of infection among horses calls for drastic measures in the way of prevention of further spread. The United States promptly established an absolute quarantine against all animals from infected ports. The authors hold that in the already infected territory ordinances should be made requiring the immediate report of all sick horses, and all those affected with surra should at once be killed. Especially valuable horses should be kept in fly-screened stalls. Horses should not be allowed to stand in large groups where infection from one can be transmitted quickly to all by the flies. Dead horses should be taken to a crematory in fly-proof wagons, or covered with earth. All sores on horses should be kept covered with a fly-proof ointment.

Trypanosomiasis acquires somewhat more interest than attaches to veterinary matters in general, by the recent discovery by Castellani, of the genus in the cerebrospinal fluid and blood of 70 per cent. of persons suffering from the sleeping sickness of Africa. Before this, trypanosomiasis was all but unknown in man. Concerning Castellani's find, Sambon says (*Journal of Tropical Medicine*, July 1, 1903) that it suggests a very definite line of research in the way of prevention, which is all the more nec-

essary as, like the surra of horses, "sleeping sickness" is invariably fatal. Concerning the probable mode of transmission, Sambon seems to regard the tsetse fly as the probable carrier of the infection. As we showed in our issue of August 15, sleeping sickness is extending its range over Africa, and, as Sambon says, its advance "is a serious menace to the development and prosperity of the great African continent, and no pains should be spared, no money withheld, no stones left unturned in order to elucidate as soon as possible the etiology of this formidable disease." At the recent meeting of the British Medical Association an entire session of the Section of Tropical Diseases was devoted to a discussion of this subject.

## VICTORIES OF MODERN SCIENCE.

This subject is becoming somewhat trite, and of late has been made the text of many a sermon in which the deeds of the men of science of the past century have been extolled to a perhaps exaggerated degree. It might be well in this age of self-laudation to bear in mind that great men lived before Agamemnon. Nevertheless, there is no getting away from the fact that there have been in the hundred years gone by some of the most conspicuous examples of men eminent in science. Of these Pasteur may be allotted one of the foremost places if not the very foremost place.

In the *Booklover's Magasine* for August, Dr. Joseph Walsh of Philadelphia gives a good sketch of some of the victories of modern science, and refers to Pasteur as one of the giants in this field. He truly says of Pasteur that all his discoveries were fundamental in character, and it is the results accomplished since, through the knowledge of them that must be considered. Pasteur, in fact, laid the foundation upon which other men built. Lister was the first to build, and he builded so well that his name more than that of any other man will go down to posterity linked with that of Pasteur as among the greatest benefactors of the human race. Dr. Walsh states that in his opinion the discovery that has proven most beneficial as a result of Pasteur's original work was the discovery of the bacillus of tuberculosis. No one can possibly have any disposition to underrate the great service which Dr. Koch has rendered to humanity by the aid of science, but to say that his discovery of the tubercle bacillus was more beneficial to the human race than that of antisepsis by Lister is too high praise.

Dr. H. T. Bulstrode, writing in *The Lancet*, August 1, on pulmonary tuberculosis, says: "In connection with the subject of the control of tuberculosis, there is, I venture to think, too great a tendency to assume that the discovery of the tubercle bacillus has fundamentally changed the face of affairs. But this is in no sense the case. The natural history of the disease has not become modified merely because we have unearthed one of the essential agents by which nature works her ends. . . . Do not let us accept without further examination the view that the reduction of the disease has been the result in the main of the discovery of the tubercle bacillus, because this is, it seems to me, a view which is not unlikely to concentrate our efforts too much upon one side of the problem." Dr. Walsh draws attention to the researches of a man to whom the English-speaking race has hardly paid the honor that is justly his due. Ramon y Cayal of Madrid has, as Dr. Walsh says, revolutionized the theories and the mechanism of nerve function. Cayal has shown "that the specific brain cell is an independent unit provided with multiple processes by means of which it is capable of acting not through one nerve alone, but through several." With reference to the fact that Fitz of Boston was the first to define appendicitis, Dr. Walsh points out that it is a curious but frequent occurrence, that it is not the man who sees the greatest number of cases of a particular kind who discovers its origin, but usually the one who sees only a few. It was so with Fitz and appendicitis. Although the victories of modern science have been remarkable, there is every reason to believe that in the future they will be even more remarkable. In some branches the fringe has only been touched.

### The Prevalence of Ankylostomiasis.

The parasite known as Ankylostoma duodenale, or Uncinaria duodenalis, is, in all likelihood, far more widely distributed than it is generally believed to be. Cases of infection with this parasite have recently come under medical observation in parts of the world widely separated. Dr. Clemow, in his work treating of the geography of disease, has a very thorough description of the distribution of the hookworm, and is of the opinion that although its known distribution is a wide one, it is probable that its actual distribution is still wider. But a short time ago the parasite was unknown in the British Isles. Recently, however, a grave epidemic of ankylostomiasis occurred in a Cornish mine. It has appeared amongst miners in certain districts of France, as also in Belgium and in Germany. Opinions differ as to how the parasite gained access to these countries. German writers declare that it was by the agency of laborers, who had become infected whilst working in the St. Gothard tunnel. Sonsino takes the view that before the outbreak of the disease in the St. Gothard tunnel, the parasite responsible for that epidemic was already diffused among certain classes of workmen in the northern countries of Europe, such as France, Belgium, Germany, Holland and Austria, as well as in Italy and in more southern countries. Nevertheless, Dr. Clemow says that he has not been able to confirm this mention of the existence of the parasite in Holland. The affection is supposed to be common in Hungary, and occurs with frequency in many parts of Italy. In those parts of Asia from which information with regard to the presence of the parasite has been obtained, the fact is gathered that it is exceedingly common.

Australia is not free from the ankylostoma, while it is extremely prevalent in most localities in Africa where any effort has been made to detect it. In the Southern States of the United States this nematode is the origin of much sickness, and it has recently been found to exist in Central America. Throughout the West India Islands the worm prevails to a greater or less extent, and the same report may be given of South America, although some portions of both the latter region and of the West India Islands would appear to be free from the pest.

As to the different factors concerned in the geographical distribution of the ankylostoma, space is lacking to refer to all. Dr. Clemow states that "there appears to be little room for doubt that the soil plays an important part in the life-history of the

animal and in its transmission to man." Again, he says: "The spread of the worm and the disease caused by it over the earth's surface, is brought about mainly, if not solely, by the movement of infected human beings." Great interest is being taken at the present time in everything relating to the ankylostoma, both in this country and elsewhere.

In Egypt experiments have been carried on recently which showed that pani-ghao, or ground-itch, is due, in many cases, to the penetration of ankylostoma larvæ into the skin of the sufferer. It might be thought that to check the spread of hookworm infection should not be very difficult of accomplishment, even if it were impossible to extirpate the parasites. It is disconcerting to find that ankylostomiasis is becoming more prevalent.

### Child Labor in New Jersey.

The laws controlling child labor are admittedly in a very unsatisfactory, not to say disgraceful, condition in many parts of the United States. This matter has been referred to in the Medical Record on several occasions. Pennsylvania, Georgia, and South Carolina are among the States which have gained an unsavory reputation for the manner in which the rights of children are neglected. Illinois, which also possessed an unenviable notoriety for its treatment of young workers, has delivered herself from this reproach by the passage of a most enlightened statute.

Under the heading "Child Labor and Compulsory Education; the Default of Philanthropy," Mrs. Florence Kelly gave an address, on July 11, before the Summer School in Philanthropic Work. The speaker selected New Jersey as an illustration of the default in philanthropy, with regard to the labor conditions of children, and because it shows the result of unaided endeavor of trade unions to protect children. It appears that New Jersey was the second State in the Union to enact a child labor law, while, at the present time, New Jersey has, according to the Census of 1900, 8,042 children under the age of sixteen years engaged in manufacture, ranking in this respect between South Carolina and Georgia. In 1892 New Jersey brought in a law limiting the hours of work for women and minors under eighteen years of age to not more than ten hours a day on five days in the week, and making the Saturday half-holiday compulsory. This humane law, which has never been repealed or pronounced unconstitutional, has nevertheless been rendered almost of no effect by wholesale exemption, followed by non-enforcement. The officers appointed to enforce the factory laws are indifferent as to whether the laws are kept or not, and it is only in those factories in which there is a strong labor organization, that the law is obeyed, and the Saturday half-day is granted. In most of the industries employing large numbers of women and children the labor organization is not strong, and thus it happens that the greater part of women and children working in factories in New Jersey are at the mercy of their employers as regards their hours of toil. Reform in the laws relating to child labor is urgently needed in many parts of this country. Philanthropists will find ample scope for the practical expression of their charitable impulses in this connection.

### The Instinct to Masticate.

Dr. Harry Campbell contributed to *The Lancet*, July 18, the first part of an article entitled "Observations on Mastication." Writing of instinct to masticate, he notes that the maxillary apparatus of man has for long ages past been put to vigorous use, and that therefore it is not surprising that the need to exercise it should express itself as a powerful instinct. He then proceeds to consider the many and curious ways in which this instinct manifests itself. "During the early months of life the natural function of feeding at the breast provides the infant's jaws, tongue, and lips with all the needful exercise. This bottle-feeding fails to do, and we frequently find bottle-fed children seeking to satisfy the natural instinct by sucking their thumbs, fingers, or any convenient object to hand. The teeth are a provision for biting hard foods, but even before they actually appear we find the child seeking to exercise his toothless gums on any hard substance he can lay hold of, and there can be no doubt that exercise of this kind tends to facilitate the eruption of the teeth, a truth, indeed, recognized universally, whether by the primitive mother who strings the tooth of some wild animal round the neck of her infant, or the up-to-date parent who provides her child with a bejeweled ivory or coral bauble. When the teeth have erupted the masticatory instinct finds among primitive peoples abundant satisfaction in the chewing of the coarse, hard foods which constitute their dietary; but among us moderns, subsisting as we do mainly on soft foods, affording but little exercise for the masticatory apparatus, it does not find its proper expression, and thus tends to die out. Nevertheless, it dies a hard death and long continues to assert itself; witness the tendency of children to bite their pencils and pen-holders."

The chewing instinct may be observed to a greater or less extent in all parts of the world. In England, although adults seldom chew, yet children will chew India rubber for hours.

Dr. Campbell says that the habit of gum chewing so common in this country comes down from far-off times, for the aborigines of Australia chew several kinds of gum, and the Patagonians are said to keep their teeth white and clean by chewing matri, a gum which exudes from the incense bush. Reference is made by the writer to betel chewing, so widespread a custom in the far East. This leaf has, doubtless, stimulating properties, for which reason also tobacco chewing is extensively practised.

In concluding his allusions to the instinct of mastication Dr. Campbell states, that the grinding of the teeth which takes place during sleep in disturbed states of the nervous system is a true masticatory act in which the normal lateral movement of the mandible is well marked, and it may thus be regarded as a perverted manifestation of the masticatory instinct.

**Arteritis in Typhoid Fever.**—W. J. Thayer calls attention to a complication of typhoid fever, which, though it has been recognized for a good many years, is little known in this country. It consists (in addition to the venous thrombus which is so commonly seen) of an arterial thrombosis apart from the cases of embolism that one sometimes sees, and is apparently associated with an active arteritis. The clinical picture is a fairly definite one—tenderness coming on toward the end of a typhoid fever, along one of the large peripheral vessels, associated with tenderness and swelling, with diminution of pulsation in the artery below that point, and eventually, either the development of dry gangrene or a slow abatement of these symptoms and complete recovery. The probability is that most of the cases are due either to secondary infection or the actual localization of the bacilli in the walls of the vessels. —*Virginia Medical Semi-Monthly.*

# News of the Week.

**A Memorial to the Late Major Walter Reed.**—On August 15 a meeting was held in Bar Harbor of friends of the late Major Reed, M.D., U. S. A., to whose investigations in so large measure was due the demonstration of the mode by which yellow fever is spread—a demonstration which had as its immediate result the suppression of that disease in the Island of Cuba. Representative men were present from different parts of the country and letters were received from various members of committees already appointed to promote the collection of a memorial fund in grateful commemoration of Dr. Reed's services. Important suggestions were presented from President Eliot, Dr. W. W. Keen, Prof. J. W. Mallet, and others. Dr. Daniel C. Gilman, chairman of a committee appointed by the American Association for the Advancement of Science, presided, and Dr. Stuart Paton acted as secretary. Among those who took part in the conference were Dr. W. H. Welch of Baltimore, Dr. Janeway of New York, Dr. Abbott of Philadelphia, Dr. Herter of New York, Dr. Barker of Chicago, Dr. Putnam of Buffalo, Dr. Fremont Smith of Bar Harbor, and Dr. Sajous of Philadelphia; and besides these medical gentlemen, Bishop Lawrence of Massachusetts and Messrs. Morris K. Jesup, President of the New York Chamber of Commerce; John S. Kennedy, President of the Presbyterian Hospital of New York, and William J. Schieffelin of New York. It was determined to raise a memorial fund of $25,000 or more, the income to be given to the widow and daughter of Dr. Reed, and after their decease the principal to be appropriated either to the promotion of researches in Dr. Reed's special field, or to the erection of a memorial in his honor at Washington. Arrangements were made for the publication of circulars explaining this movement, and asking coöperation not only from the medical profession, but from all liberally disposed individuals who appreciate the value of Dr. Reed's services to his country and to mankind.

**To Reduce Infant Mortality.**—Dr. Edward Martin, Director of Charities and Public Health of Philadelphia, has organized a series of lectures by a dozen or more physicians, to be delivered to mothers in the congested districts on the care of children particularly, but discussing also other hygienic matters.

**Typhoid Fever and Smallpox in Philadelphia.**—For the week ended August 15 there were reported to the Philadelphia Board of Health 91 cases of typhoid fever with 14 deaths, and 16 cases of smallpox with 7 deaths, as compared with 108 cases of the former and 36 cases of the latter for the preceding week. The number of cases of diphtheria and scarlet fever was approximately unchanged, being 49 for former and 63 for the latter. The total number of deaths was 426 as compared with 423 for the preceding week and 446 for the corresponding week of the previous year. The number of cases of typhoid fever reported for the week ended August 22 was 118, with 18 deaths, as compared with 91 cases and 14 deaths for the preceding week. There were reported also 20 cases of smallpox, with 2 deaths, as against 16 cases and 7 deaths for the preceding week. The total number of deaths from all causes was 422, as compared with 426 for the preceding week and 379 for the corresponding week of the previous year.

**The Therapeutics of Chewing Gum.**—Among the contracts recently awarded by the Minnesota State Board of Control is one for a large quantity of chewing gum, and an investigation instituted by the curious has shown that this is for use in the State hospitals for the insane. It is stated that in many instances patients in a state of violent excitement are quieted by giving them gum to chew, and those who are too distracted to be put to any employment are made fit for work by the same means.

**A Good Samaritan in Trouble.**—A woman was struck by an automobile and rendered unconscious a few days ago, and among the witnesses of the accident was a physician in the neighborhood. In his zeal to assist the unfortunate he knelt over the woman and began his ministrations without explanation to the husband. The latter mistaking his motives and thinking he was intent on robbery, struck him and an encounter followed which landed the two in the police station. The moral is obvious.

**A Leprosy Scare in Porto Rico.**—Acting Governor Hartzell of Porto Rico has suspended the superintendent of the leper colony and his assistant, on the strength of a report recently made by the Acting Director of Charities. According to this report, chickens and pigs raised by lepers have been freely sold in San Juan, and paper money which has been passed from hand to hand in the leper colony has been allowed to enter into circulation in other parts of the island.

**An International Congress for the Study of Tuberculosis** will be held in Paris from September 24 to October 1, 1904. The Congress will comprise a Medical, a Social, and a Technical Section. In the Medical Section the following are the questions proposed for discussion: (1) The treatment of lupus by the new methods; (2) the early diagnosis of tuberculosis by the new methods; (3) comparative study of the different forms of tuberculosis. The Social Section will discuss the following questions: (1) The etiological factors of tuberculosis; (2) the value of the various methods of treating tuberculosis; (3) assurance and sickness societies in relation to the struggle against tuberculosis. The Technical Section consists of a museum in which will be exhibited collections of anatomopathological, histological, and bacteriological specimens and preparations; tables of statistics, plans, and designs for the installation of hospitals, sanatoria, and dispensaries; publications of all kinds relative to antituberculosis leagues and associations; and industrial products used in the treatment of tuberculosis. The President of the Congress is Professor Brouardel.—*The British Medical Journal.*

**A Baby Incubator,** such as the one exhibited at the Pan-American Exposition at Buffalo, has been in operation at Coney Island this summer. The Society for the Prevention of Cruelty to Children recently caused the arrest of one of the proprietors of the incubator exhibit, for running a "baby farm." The case was brought to the Coney Island Court, and to decide upon the merits of the apparatus the Mayor appointed a committee of health officials, which reported that the incubator was doing good and recommended its continuance.

**An Early Observation on the Prophylactic Value of the Mosquito Bar.**—In *The Lancet* for June 20 is the following quotation which a correspondent found in the *Edinburgh Review* for August, 1822: "It was lately observed casually that some persons who slept in one of these pestilential spots in Italy under a canopeum or mosquito net *escaped* the effects of the miasm, whilst those *unprovided* with this expedient took the disease" (*i.e.* Roman ague or malaria). Dr. G. Brocchi, "*Dello Stato Fisico del Suolo di Roma.*" The correspondent adds that the reviewer designates it, "if true, as one of the

most valuable discoveries in modern times in prophylaxis," but that the explanation "that the air breathed and expired by the sleeper acts as an antiseptic, being kept enclosed under the canopeum," is, of course, fanciful and absurd.

**The Medical Society of Virginia.**—The thirty-fourth annual meeting of this society will be held in Roanoke on September 15, 16, and 17, 1903. The program, recently published, presages an interesting and instructive meeting. Several excursions and receptions in honor of the members of the society and invited guests, with the ladies of their families, have been planned. On the morning of Wednesday, September 16, there will be a general discussion on the "Diagnosis of Gastric Affections," to be opened by Drs. John H. Musser of Philadelphia, E. C. Hopkins of Richmond, and John C. Hemmeter of Baltimore. The president of the society is Dr John N. Upshur of Richmond, the recording secretary is Dr. Landon B. Edwards of Richmond, and the chairman of the committee of arrangements is Dr. J. Newton Lewis of Roanoke.

**The Late Pope's Physicians.**—Cardinal Oreglia, Camerlengo of the Papal Court, has paid the fees of the physicians who attended Pope Leo XIII during his last illness. The amounts are said to have been as follows: £800 to Dr. Lapponi, £600 to Professor Mazzoni, and £400 to Professor Rossoni. The new Pope has appointed Dr. Lapponi to be his Physician in Ordinary.

**The Fifth International Dermatological Congress** will meet in Berlin, Germany, September 13–17, 1904. The following subjects have been selected by the officers of the congress for discussion: (1) The syphilitic affections of the circulatory apparatus; (2) The diseases of the skin in anomalies of metabolism; (3) Epitheliomas and their treatment. Dr. James Nevins Hyde of Chicago is the secretary for America.

**The Jenner Institute of Preventive Medicine.**—It has been decided to drop the name of Jenner from this institution and substitute that of Lister, so that it will hereafter be known as the Lister Institute of Preventive Medicine. The reason for this change of name is said to be that there was already an institution in existence called after Jenner, and as it was first in the field it claimed the right to keep its name.

**Scarcity of Cod-liver Oil.**—The price ot Norwegian cod-liver oil has risen from $22 to $160 a barrel, and the demand far outruns the supply. It was said, when the price first began to go up, that a corner had been formed, but now it is asserted that there is a genuine scarcity, the yield being only about 4 per cent. of the normal. Most of the oil used for medicinal purposes comes from the fisheries of the Lofoden Islands off the west coast of Norway. The normal annual yield here is 30,000 barrels of crude oil, but this year, it is said, only 1,200 barrels have been obtained. The catch of cod is as large as usual, but the livers hold little fat. This is ascribed to the unusual low temperature of the water on the fishing grounds, in consequence of which the crustaceans which constitute the oil-producing food of the cod have been reduced in quantity.

**The True Scientific Spirit.**—Professor Langley of the Smithsonian Institute, who has been engaged in the construction of a flying machine on new principles, or rather on the old principles of the eagle's flight, has made himself unpopular with certain of the newspapers whose reporters have sought to learn his secret and explain the construction of his machine. He has endeavored to meet the charge that he was withholding what the public ought, or at least wanted, to know by showing that premature publication would be undesirable in every way. "It is the practice of all scientific men," he says, "indeed of all prudent men, not to make public the results of their work till these are certain. This consideration and not any desire to withhold from the public matters in which the public is interested has dictated the policy thus far pursued here. The fullest publicity consistent with the national interest (since these recent experiments have for their object the development of a machine for war purposes) will be given to this work when it reaches a stage which warrants publication." Some workers in other departments of science might with profit ponder on these words.

**Dr. J. C. Pryor,** Past-Assistant Surgeon U. S. Navy, serving on the gunboat *Bancroft*, has been commended in a letter to the Navy Department by Lieutenant-Commander Culver, for conspicuous service in saving the lives of wounded Venezuelans at the recent storming of Ciudad Bolivar by the government forces.

**Stony Wold Sanatorium** at Lake Kushaqua, Franklin County, N. Y., was formally opened by appropriate ceremonies on August 15. About a hundred physicians and others interested in philanthropic work, especially those actively engaged in the war on tuberculosis, were present. Addresses were made by Bishop Henry C. Potter of the Episcopal Diocese of New York, Mr. Frederick B. Jennings, chairman of the building committee, and Dr. E. L. Trudeau of the Adirondack Cottage Sanatorium.

**New Building for the Jersey City Hospital.**—The Jersey City Board of Finance has appropriated $200,000 for the erection of a new city hospital. The hospital will be on the site of the present building at Baldwin avenue and Montgomery street, with an additional plot on the south side. The plans have already been prepared by C. P. Long, city architect. The new building will be 40x121 feet, three stories high. There will also be additional buildings for insane and alcoholic patients and consumptives. Besides these there will be a morgue, stable, and power-house for electric lighting. All the buildings will be erected under the supervision of Mayor Fagan and the hospital trustees, Dr. George W. Shera, Dr. F. E. Lambert, E. M. Watson, Andrew Phelan, and Henry Vogel.

**A New Woman's Hospital.**—The plans for the new buildings to be erected for the Woman's Hospital to replace the old building at Lexington avenue and Fiftieth street, have been filed with the Building Superintendent. The building will be six stories, with basement and attic, and have facade of granite, limestone, and terra cotta. It will be 188 feet front and 40 feet deep, with two wings each 40 feet wide and 60 feet deep, and will be on One Hundred and Tenth street, east of Amsterdam avenue. The first floor will contain, besides the administration offices, a lecture hall, and a chapel with a seating capacity of 144. The second floor will be fitted up as a dormitory for nurses, and the third floor will contain the private wards. Each of the wings of the fourth floor will contain forty beds, and there will be ten endowed beds in the main building on this floor. The fifth floor will have a critical ward with twenty beds, the sixth floor will contain the living rooms of the physicians and other officials, in the attic will be the servants' quarters, and in the basement will be a museum and an out-patient department. The cost is estimated at $610,000.

**Extirpating Malaria in the Soudan.**—A cable despatch to *The Sun* quotes from an interesting report by Surgeon-Major Penton, chief medical officer of the British forces in the Soudan, describing the results of the campaign against mosquitos in that region. Ismailia, he says, is now practically free of mosquitos and nets may almost be dispensed with. Two swamps northeast of the town and others on the south have been filled up with sand, while a third large marsh to the north has been well drained. Workmen are still filling up the pools and mowing the coarse undergrowth. At first they were worried in the evenings by the swarms of mosquitos, but lately they have seen scarcely any. Statistics in regard to the health of Ismailia show that from January 1 to June 30, 1903, there were only three cases of malaria in the hospitals, as compared with 52 in the corresponding period of 1902. While throughout Ismailia there were 569 cases from January 1 to May 30, 1902, the average for the same period in 1903 was only 72. Many of these cases were probably relapses from previous cases. Major Penton suggests that when the present operations against mosquitos are completed malarial fever will practically have disappeared.

**Modified Open-air Treatment.**—In Brighton, England, a novel plan has been devised by Dr. Arthur Newsholme, the medical officer of health, for giving assistance to consumptives who are dependent on the town for their treatment. Patients are sent for a month at a time to the Borough Sanatorium for a modified open-air treatment. The main object is not to cure the patient in this single month, but to teach him how to live after he returns home. Meanwhile his house is disinfected, and on his return he takes up his life under improved conditions. In cases in which a longer stay is practicable and particularly desirable, it is arranged for. But this limited stay brings about in most instances marked improvement, prolonging the patient's period of usefulness, and at the same time makes it possible for a large number of persons to be benefited, decreasing proportionately for the community the danger of infection.—*Charities.*

**A Suicide by the "Water Cure" Method.**—A prisoner patient in the Holy Cross Hospital, Salt Lake City, recently adopted a method, called the "water cure" in the Philippines, for ending his own life. Evading his nurse he went into a bathroom, got into the tub, and, placing his mouth over the faucet, turned the water on full force. He clenched the faucet between his teeth until unconscious. He died within a few minutes.

**Obituary Notes.**—Dr. PHANETT C. BARKER of Morristown, N. J., died on August 21, after a short illness. He was sixty-nine years of age, and had passed nearly his entire professional life, since his graduation from the College of Physicians and Surgeons, New York, in 1860, in Morristown. About twelve years ago he founded the Morristown Memorial Hospital Association, which built the fine hospital of that name and of which he was a director up to the time of his death.

Dr. ALLEN R. THOMPSON of Troy, N. Y., died at Asbury Park, N. J., on August 22. He studied medicine with his father and was graduated from the Albany Medical College in the class of 1883. He was appointed police surgeon in 1895, and in the same year was elected Coroner of Rensselaer county on the Republican ticket. In 1898 he was reëlected, being the only successful Republican candidate in the county. He was elected County Clerk in 1901 and held that position at the time of his death. He had been in poor health for about a year.

# Correspondence.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

ECHOES FROM SWANSEA—THE ROYAL TOUR IN IRELAND.

LONDON, August 8, 1903.

THE visit of the British Medical Association to Swansea shifted for a few days the center of medical gossip to that somewhat remote town with its busy manufactures and docks, its pleasant suburbs along the bay, and its Welsh associations. Just fifty years ago the then comparatively insignificant Provincial Medical Association assembled at Swansea for its annual meeting. The development into the present widespread society is matter of history. From all those I have seen since their return I hear that this seventy-first anniversary was fairly successful, but, of course, not the equal of the meetings in the most popular places. Still some 700 persons put in an appearance for the doctors' picnic, and some good sectional work was done by the more industrious members. If no striking announcement was made it is accepted as only natural, since brilliant discoveries are not to be had to order.

Your own reporters have kept you informed of the serious work, and the numerous entertainments provided by the hospitable Welsh will be of minor interest to your readers. The hard work of the entertainment committee evidently deserved all the praise they received, and which is being repeated now in conjunction with recognition of Welsh hospitality. There will be a great change of environment next year, for the meeting has been fixed to be held at Oxford, the senior physician of the Radcliffe Infirmary being appointed president-elect.

The annual museum offered the usual assortment of drugs, chemicals, foods, and appliances. Samples were as freely distributed as usual, and a certain proportion of members seem to take special interest in the exhibition. Here again, from all I gather, I feel convinced that one exhibition very closely resembles another, so in that respect one does not lose much by being detained in London with the four millions of inhabitants who occupy the city when you hear continually that it is empty.

The medico-political committee of the association in its report plumes itself on what it has done during the period of transition, and on the more frequent resort to it as a body possessing some representative authority. A number of matters are stated to have been brought before the committee by bodies of medical men unconnected with the association. This kind of relation seems to have been mutually satisfactory, the committee receiving valuable information and assistance from some societies and being in turn able to promote their objects.

The annual dinner was fairly well attended, the president occupying the chair, and the usual toasts being heartily drunk. In the morning of the same day (Thursday) the Temperance Breakfast was once more given by the National Temperance League. Dr. Rawlings of Swansea occupied the chair and was supported by Dr. Griffiths, president of the British Medical Association, Sir V. Horsley, and about 100 other members. On this same day the Continental Anglo-American Medical Society met together for luncheon. Clearly the demands for supplies were as well met as for amusement and science. I hear that all these things succeeded—especially amusements—and that the character of picnic was as pronounced as ever, perhaps more.

The public seem to have taken interest in the discussion on vaccination which took place in the Section of State Medicine. Consequently, the general newspapers have had their say on the matter. Dr. McVail, as president of the section, gave one of his trenchant addresses on this subject, on which he is so great an authority. He was well supported by such veteran sanitarians as Drs. Davies, Honder, Morris, Doysdale, Mole, Rankin, Brierley. On the motion of the chairman, the council of the association was urged to use all its machinery for bringing before members of Parliament the need of further legislation. It was next resolved, on the motion of Dr. Drysdale, that "considering that of late years there have occurred in several cities of the United Kingdom epidemics of smallpox, while in Germany, since 1875, such epidemics have been unheard of on account of the fact that infants are vaccinated and children revaccinated before their twelfth year, this meeting is of opinion that all children should be vaccinated in infancy and revaccinated at the age of ten or twelve."

Perhaps the most far-reaching act of the Swansea meeting was a resolution of the council of the association to appoint a committee to consider the question of undertaking medical defence. It is a question which has long been agitated in the association, and on which the members at present seem much divided in opinion.

The visit of the King and Queen to Ireland has brought

again into prominence their majesties' interest in hospitals and charities. Among the honors conferred on the occasion, knighthoods have been allotted to the presidents of the two royal colleges, Dublin; Dr. Macan, P.R.C.P., and Mr. Lambert Ormsby, P.R.C.S.

Lord Iveagh, to commemorate the occasion, presented the King with £20,000 to divide among the Dublin hospitals and the Newcastle Consumption Hospital in the county of Wicklow.

## THE PHYSICAL BASIS OF LIFE.

To the Editor of the Medical Record:

Sir: In your issue of August 1 appears a "lay sermon" by Dr. Axel E. Gibson, with Huxley's "Physical Basis of Life" as its text. The eloquence and erudition displayed in this discourse, with its suggestion of "world problems," justifies attention to certain errors that appear in the opening paragraphs. The essayist identifies the "gemmules" of Darwin, "plastidules" of Haeckel, and "physiologic units" of Spencer, with the microsomes of the cell body. There is really no warrant for such statement. as the philosophers mentioned merely postulated the existence of certain invisible units intermediate between the chemical unit and the morphological unit or cell, and in no way identified these purely philosophical abstractions with any visible microscopical element in the cell, and certainly not with microsomes outside of the nucleus. Boveri, Lalage, and other eminent cytologists have clearly shown that the physical basis of heredity lies in the nucleus, although the cytoplasm itself is doubtless profoundly affected by emanations or projections from that body. It is true that other philosophers and biologists have also brought forward theories of physiological units, and some of them, notably Weismann, have identified *aggregations* of these invisible units or "biophores" as the chromatin granules or "ids" of the cell nucleus.

Weismann with his biophores, determinants, ids, idants, etc., has given a positive aspect to his development of Darwin's theory of pangenesis, which the latter could not possibly have done, as his views were deduced from general laws and phenomena, and not the result of exact cytological research. Few physicians or scientists, however, are inclined to accept Weismann's conclusions involving, as they do, a negation of the possible transmission of functionally acquired characteristics. Herbert Spencer frankly admits that his own theory of physiological units is a very inadequate working hypothesis, insufficient to account for processes which probably lie beyond our cognition.

The dogmatic form given to the views of these philosophers is liable to prove misleading and confusing to some eager student of life's mysteries.

## Progress of Medical Science.

*Boston Medical and Surgical Journal, August 20, 1903.*

**Medical Treatment of Gastric Ulcer.**—Hubert G. Wilbur says that the main indications which present themselves in the treatment of ulcer of the stomach are (1) to secure rest in bed, that the strength may be saved; and (2) to obtain absolute rest for the stomach until pain, vomiting, and hemorrhage are relieved, relying on nourishment by the bowel to maintain the vital force. Food causes pain by irritating the sensory nerves at the abraded surface, incites to vomiting through the necessity which the stomach feels to eject the mass which it is unable to digest, causes excessive secretion of gastric juice which in itself aggravates the ulcer, and at the same time stimulates the peristaltic action of the muscular coat whereby the liability to hemorrhage is increased. Hence arises the necessity for absolute abstention from all food and drink for at least three or four days. In cases of tormenting thirst small pieces of cracked ice may be given, or the effect of an enema of water may be given. Pain may be relieved by the external application of a flannel compress dipped in a mixture of chloroform, one part, and alcohol, three parts. Obstinate vomiting will sometimes yield to an enema containing sodium bromide, gr. 80, and extract of cannabis indica., gr. ½. In rectal feeding a small amount of concentrated food should be given not oftener than once in eight hours, until a tolerance of the enemata is established. Feeding by the bowel may be continued, when necessary, for at least ten days or two weeks, when a gradual return to stomach feeding may be begun. It is usually necessary to add iron to the food given by enema. In returning to stomach feeding great care must be observed for a long period to give only bland food, avoiding all brown bread, course vegetables, fruits, and other materials which may irritate the vulnerable mucous membrane. Hemorrhage is best combated by turpentine in doses of ♏ xx to xxx of a mixture of two ounces of turpentine beaten up with the white of one egg. In cases of very profuse bleeding, the colon should be flooded with hot salt-solution, a drachm to the pint, and digitalin and strychnine should be given hypodermically.

**Surgical Treatment of Gastric Ulcer.**—John C. Munro urges a more intimate coöperation of the physician and the surgeon in the management of a case of ulcer of the stomach. He grants willingly that the majority of simple gastric ulcer are best treated and cured by the physician, but holds firmly that it is the duty of the latter to seek surgical advice in all obviously serious and obstinate cases. He quotes Mikulicz that "the danger to life from gastric ulcer is at least not less but probably far greater than the danger of a complete modern operation," and he predicts that his plea for more frequent and earlier operation in cases of ulcer of the stomach will, within five years, be considered mild and conservative by the very men who may to-day set him down as too radical. Before condemning operation for ulcer of the stomach because of the discouraging results of operations in the past, we must remember, the writer contends, that there are certain fundamental facts recognized by the surgeon, but not yet fully appreciated by the physician. An operation as performed on the average patient with a mortality so small that it may practically be disregarded becomes serious or even unjustifiable if done in the presence of persistent hemorrhage, prolonged sepsis, starvation, absorption of ptomains, etc. This emphasizes the need of early operation. And even granting the surgical errors of the past, we must not lose sight of the fact that eventually we are to look to surgery for the relief or cure of ulcers incurable by medical means, for the prevention or cure of the malignant degenerations and for relief from the thousand and one distressing sequelæ that do not kill, but that make life worse than death. Up to the present time surgery has by no means solved the whole question of the treatment of ulcer or its complications. There is much still to be learned before we can fairly say that a beginning has been made, but the process of learning must go on with the physician and the surgeon working conjointly in practically all cases of ulcer or suspected ulcer. Later, when both surgeon and physician are educated sufficiently, as is now the case in appendicitis for the most part, to enable each to recognize what types are medical and what are surgical, the combined observation will be demanded in a small proportion only of all cases. This is the ideal for which we must strive.

*Journal of the American Medical Association, Aug. 22, 1903.*

**The Apparent Immunizing Value of Attenuated Tubercle Bacilli.**—E. A. de Schweinitz reviews his earlier work in the belief that if proper attention were given to it there would be less tendency in some quarters to assume an absolute difference between tubercle bacilli obtained from men and those obtained from cattle. He recalls the fact that, in his work published in 1894, he was the first to show that guinea-pigs, that had received large doses of human tubercle bacilli that had largely lost their virulence, were rendered resistant and immune to subsequent inoculations with tuberculous material of bovine origin. Later experiments on cattle are described, and the conclusion is reached that, as these researches show the possibility of vaccinating against bovine tuberculosis by means of tubercle bacilli of human origin, the question at issue narrows itself down to variations in degree of virulence of tubercle bacilli, rather than to differences in the tubercle bacilli themselves. Moreover, the readiness with which bovine, as well as human, tubercle bacilli may be attenuated goes still further to prove the intimate relationship of bacilli obtained from various sources, and emphasizes the influence of environment on the virulence of the bacilli.

**Trigeminal Neuralgia Treated by Intraneural Injections of Osmic Acid.**—John B. Murphy reports a case in which this comparatively new treatment, recommended by W. H. Bennett of London, in 1899, was employed. The patient was a man of seventy-six, the victim of neuralgia for about thirty years. The operation was done on June 11, 1903, under local anæsthesia. The supra- and infra-orbital and mental nerves were exposed, elevated with a blunt hook, and, with a fine hypodermic needle, injected with a few minims of a fresh 1.5 per cent. solution of osmic acid. The wound healed by primary union, and the patient left the hospital well on June 20. When heard from, on July 21, there had been no recurrence of the pain. The manner of action of osmic acid is not understood, but the author inclines to the opinion that the acid produces a degeneration of the nerve on the proximal side of the infection, toward the ganglion, because the pain does not

usually subside completely immediately after the operation as it would if the osmic acid produced only a local destructive effect. Moreover, the relief from pain in the reported cases has been permanent, a result which is very different from that observed after peripheral resection.

**Recent Investigation Bearing on Infectious Diseases of Unknown Etiology.**—Ludwig Hektoen draws the following conclusions from this study: (1) Clinical and experimental observations furnish strong evidence, and in some cases absolute proof, that certain transmissible human and animal diseases of unknown etiology are not toxic, but infectious—that is, caused by living organisms capable of proliferation and metabolic activities. (2) In the case of the human diseases of this group, knowledge is farthest advanced in regard to those that are communicable to animals, viz., hydrophobia, vaccinia, and smallpox—and experiments on human beings have shown that the case of yellow fever occurs in the blood, passes through Berkefeld filters, the filtrate being bacteriologically sterile, according to present method, and that infection occurs through the medium of mosquitos (*Stegomyia fasciata*). (3) Certain morphologic elements in the lesions of vaccinia and smallpox are regarded by some investigators of the highest standing as representing stages in the developmental cycles of protozoa. The causative agents of these diseases do not pass through bacteria-proof filters. (4) The virus of many transmissible animal diseases (foot-and-mouth disease, peripneumonia, rinderpest, sheep-pox, chicken typhus, horse sickness, epithelioma contagiosum of fowls) passes through various filters ordinarily regarded as impermeable to the smallest known bacteria, the filtrates being virulent, though giving no sign of containing visible corpuscular elements. (5) Whether these invisible and, except in peripneumonia, uncultivable viruses are all ultramiscroscopic in size, or invisible also for other reasons, has not been settled definitely; but there is much in favor of the view that they are ultramiscroscopic in size. (6) Further progress in this field may be expected from the application of methods, recently introduced by physicists, in order to furnish ocular demonstration of the existence of particles too small to be seen directly.

*The Medical News, August 22, 1903.*

**Amber Yellow Glass in the Examination and Treatment of Eyes.**—H. H. Seabrook has employed, in oblique and indirect examination of the eye, a lens of two and a half inches focal distance made from a biconvex lens of white glass split and cemented upon a plain glass of amber yellow color. With this lens there is less congestion, lacrymation, photophobia, and pain in examined eyes; it is, therefore, suitable for examination by the oblique method of lesions of the cornea, iris, and ciliary body. Discoloration of the iris with the yellow light may cause some mental confusion to the examiner before he becomes accustomed to it, and the dulled corneal reflex makes the appreciation of a foreign body upon the cornea less easy to the novice, because of diminished contrast between the foreign substance and its background. In examination of the ocular fundus by the indirect method the yellow lens is more comfortable than the white for both examining and examined eyes, and the picture of the background is not much changed by the lessened reflex from the retinal vessels. The sphincter of the iris is not contracted so much by yellow as by white light. In its therapeutic uses the method would seem likely to be of service in cases of asthenopia with hyperæsthesia of the retina, though it has not been tried sufficiently to determine what its secondary effects might be. In two cases of corneal disease with superficial central keratitis there was improved vision with the yellow glass. Patients with more peripheral corneal affections, three with ulcers, four with phlyctenular keratitis, three with pannus were not improved as regards vision, but the latter at least appeared to have less irritation; in one of these, with chronic conjunctivitis following trachoma, persistent pain, increasing in severity as the day advanced, was relieved from the first day the glasses were worn; within five days ocular congestion disappeared. Amber yellow glasses were used successfully in a case of post-operative iritis. A patient with posterior synechiæ and hazy media in both eyes showed diminished vision in one eye, but improvement in the other with yellow glass before atropine, and improvement in both after atropine. Irritation was less, and this was the result in all cases, either in simple tests of the eyes, or when the glasses were regularly worn. Two patients with chorioretinitis and vitreous opacities, one severe, one mild, showed improved vision. The most beneficial results might, perhaps, be expected in cases of diminished vision and hyperæsthesia of the retina, as occurs with glaucoma or tobacco amblyopia, and the author reports three such cases in which decided benefit followed the use of yellow glasses.

*New York Medical Journal, August 22, 1903.*

**Treatment of Papilloma of the Larynx in Children.**—J. E. Summers, Jr., reports three cases of this affection. In the first case he performed tracheotomy to relieve the urgent respiratory symptoms, and some weeks later did a tracheotomy and removed the growths, cauterizing their bases with glacial acetic acid. Four weeks later an attempt was made to remove the tracheal tube, but the dyspnœa returned so persistently that resort was had to intubation. This measure was tried in the hope that the pressure of the tube would cause absorption of the recurrent growths. So far from this happening, however, the growths increased, spreading upward until they overhung the orifice of the tube, rendering a second tracheotomy imperative. Two weeks later the larynx was again opened and the growths were removed, the base of each being curetted and cauterized. The growths returned again after this operation, but no further operative measures were undertaken, and finally the papillomata disappeared and the tube was removed permanently about two years after the first operation. In the other two cases tracheotomy alone was done, and the tubes were removed in about six months, the growths having disappeared. The author was led to report these cases by reading a review of a paper by G. Hunter Mackenzie in which it was stated that he advocated tracheotomy without attempting removal of the growths, the tracheotomy tube to be worn until the disappearance of the papilloma, generally a year or two. Summers says that the laryngoscope is an unsatisfactory instrument in diagnosticating laryngeal disease among young children, and we must, in a measure, depend upon symptoms. "Given the case of a child with the history of a slowly increasing hoarseness, followed by slight or marked aphonia and difficult breathing (the history covering weeks or several months), the diagnosis of papilloma of the larynx can be made." Tracheotomy, he says, is the most available remedy for papilloma of the larynx in children; intubation is a failure, and the justifiability of laryngotomy is questionable.

*American Medicine, August 22, 1903.*

**Successful Treatment of Morphinism.**—J. Ben. Jones reports a case of morphine addiction in a man fifty years of age, who had fallen victim to the drug by being forced to take it for the relief of sciatica. An attempt was made to cure him by sudden withdrawal, the writer having tried the plan of gradual withdrawal in previous cases without success, but the attempt failed signally, and a return to morphine was rendered imperative by symptoms of impending dissolution. After this, repeated trials were made of various advertised cures, but all these remedies evidently contained opium in some form, for in each case an immediate return to the morphine in larger doses was necessary upon discontinuing the so-called cure. The patient was finally treated after the method of Dr. George E. Pettey. This method is founded upon the theory that the essential pathology of morphinism is autotoxæmia, and the chief cause of the phenomena known as withdrawal symptoms is the presence of this toxic matter in the system and not the drug itself. The withdrawal of the drug merely permits these symptoms to develop, but it is not their principal cause. The portal system is very much engorged, thus greatly impeding the flow of blood through that system, and that the heart, deprived of the support given it by morphine is unable to propel the blood through that system against such an obstruction, and this fact accounts for the difficult heart action, oppressed breathing, profuse sweating, extreme prostration and collapse, which occur after the sudden stoppage of morphine. When the system is cleansed of the accumulated effete material, autotoxæmia overcome, and the portal system disengorged, morphine can be at once withdrawn without shock, collapse or danger to life, and the suffering incident to such withdrawal subsides in a few days. This suffering can be obviated or relieved by the administration of hyoscine for a period of from thirty-six to forty-eight hours. At the end of that time the patient will, as a rule, be free from all desire for morphine, and withdrawal symptoms will not return. Acting upon this theory, the patient's kidneys were first flushed by the free drinking of water and by the use of saline enemata. The following day, after a Turkish bath, he took at 4, 6, 8, and 10 P.M. a capsule containing calomel and powdered extract of cascara, of each 2½ grains, ipicac ½ grain, and strychnine ¼ grain. The following morning he had four very large evacuations from the bowel. The previous evening he had had his usual allowance of morphine, but from that time took no more. When the need of it began to be felt he received instead hyoscine hydrobromate in doses of $\frac{1}{150}$ to $\frac{1}{100}$ grain. The hyoscine was continued through this day, and one dose only was given the following day. No medicine of any kind was given after the fourth day, and convalescence was rapid and uninterrupted.

*The Lancet, August* 15, 1903.

**A Problem in Medicolegal Psychology.**—J. S. Mackintosh reports the case of a clergyman who, after a busy morning, and apparently amid surroundings full of happiness and free from any special worries, suddenly shot himself through the head. There was no apparent motive for this evidently unpremeditated act, and careful inquiry showed that he had that morning fallen heavily from his bicycle and had been seeming so much disabled as to be unable to mount the bicycle again. He had gone home and had carefully made his toilet with the exception of his collar and cuffs, and had then gone to the drawer for these articles. Here he had spied his revolver. The reporter is of the opinion that the fall induced that form of cerebral concussion which permits the sufferer to perform various complex and apparently reasoned acts while in a mental condition which is comparable with that of a somnambulist, the epileptic shortly after a fit, and of a certain phase of the hypnotic state. The answer to the natural query: "Why did he load the revolver and put it to his own head?" is thought to be found in a newspaper account that week of a clergyman who had shot himself through the head. The author carefully distinguishes between this mental condition and that observed in persons who destroy themselves as a result of a sudden impulse.

**A Rare Case of Intestinal Obstruction Resulting from a Kick in the Right Iliac Region.**—Gilbert Kempe and E. Kempson Brown report this case. The patient was a stable boy of seventeen years who was kicked in the right iliac region on October 8, 1902. There was no evidence of perforation of any of the hollow viscera, and his general condition remained fairly satisfactory up to the sixteenth day, when meterosim became very troublesome. Marked temporary relief was afforded by the hypodermatic use of strychnine but soon the bowel became absolutely obstructed. It was not thought safe to do more than an enterotomy and insert a Paul's tube into the part affected, the jejunum. This led to some improvement, and after he had been made stronger by both oral and rectal feeding an attempt was made on December 4 to relieve the obstruction by resection and intestinal suture. The patient's condition grew steadily worse for the next five days, so another enterotomy was done on the jejunum. Improvement did not follow for two days, and then only on injecting warm water into the proximal side of the fistula. After that convalescence was steady, and on February 16 the loop of bowel involved in the fecal fistula was excised, the distal portion closed and the proximal portion implanted into the colon by means of a Murphy button. The button came away at the end of a week. The boy completely recovered, and is now doing his ordinary work.

*British Medical Journal, August* 15, 1903.

**Simulation of a Perforating Gastric Ulcer.**—John R. Pollock reports the case of a girl, eighteen years old, who, when he first saw her, was lying in bed in a state of collapse, cold, practically pulseless, with abdominal expression well marked, and complaining of severe pain in the abdomen. On examination the abdomen was found retracted, with complete absence of abdominal respiration. On palpation the muscles were as hard as boards, and deep pressure caused great increase of pain, which was referred principally to the epigastric and left supraclavicular regions. The history given was that at 6.30 A.M. she had a cup of tea in bed, and when she had taken about half she gave a scream and said, "Oh, my stomach," and then fainted. She was given some brandy, and after a time revived, the condition above described coming on at once, accompanied with retching but no vomiting. She fainted twice during the day from pain. On the following day her condition had improved, and four days later she was practically well except for some tenderness of the muscles and pain on pressure over the left ovary. Treatment consisted in the hypodermic injection of morphine and withholding all food and drink. There had been previous attacks of sickness in conjunction with the menses, and the above attack came on on the third day of the flow, which stopped on the fifth day, her usual period lasting seven days. From the first appearances it looked like a clear case of ruptured gastric ulcer, but the subsequent course and eventual recovery showed that this was not the condition present.

**Purulent Pericarditis of Unusual Duration in a Child.**—J. A. Coutts reports the case of a child, four years old, who had been ailing and wasting for ten weeks. The child was extremely pale, with complexion of a dull yellow straw color; the finger tips were slightly bulbous and cyanosed. The liver was much enlarged, but the spleen was apparently of normal size. The child's breathing was not quickened and there was no respiratory distress. There was no orthopnœa and she was able to lie on either side with comfort. On examination of the chest there was evident diminution of expansion on the left side. On percussion there was a dull patch over the left front, extending from the supraclavicular fossa into the cardiac dulness below. This dull area was triangular in shape, with apex upward, and extended laterally from near the anterior axillary border on the left side to the right border of the sternum. Over this area there was marked resistance on percussion, the breath sounds were extremely weak and distinctly bronchial in character, and there were a number of sharp creaky crepitations when the child took a deep breath or coughed, with a doubtful pleuritic creak at times. The dull area was continuous with the cardiac dulness, which extended from one fingerbreadth outside the nipple line in the fourth left intercostal space to one inch outside the right border of the sternum. The note was dull over the third and fourth ribs for about three-quarters of an inch to the right of the sternum. The heart's apex beat was plainly felt in the fifth left intercostal space, three-quarters of an inch outside the nipple line. At the apex the sounds were galloping and weak, and near the base they were muffled but seemed pure. There was no pericardial friction sound to be heard. The possibility of a purulent pericarditis was thought of, but a diagnosis of loculated empyema was finally settled upon. At the autopsy, however, the pericardium was seen extending upward to the second space, an inch and a half to the right of the right sternal edge, and downward for some considerable extent, forming in this direction regular pockets. The pericardium was thickened, and covered all over by thick lymph, but not in the form of long villi, as one sometimes sees. There were about ten ounces of thick greenish pus, but no blood, in the sac. The pus extended chiefly into the pockets already mentioned. The heart and pericardium weighed nine and a half ounces. The heart muscle immediately beneath the epicardium was pale, but elsewhere appeared to be normal.

*Münchener medicinische Wochenschrift, August* 4, 1903.

**Metastatic Gonorrhœal Inflammations of the Eye in the Adult.**—W. Apetz reports a case in which six years after an attack of gonorrhœa a recurrence of the discharge took place accompanied by gonorrhœal joint complications and inflammations of the eyes (conjunctivitis, iritis, etc.). Several such relapses occurred. A reinfection could be absolutely excluded as could also an inoculation of the eye with the urethral discharge. The eye complications may therefore be regarded as metastatic. Several views have been advanced with respect to the nature of such gonorrhœal metastasis, but none of them rest upon a sure footing, although that which regards them as due to the latent effects of gonorrhœal toxins seems the most probable.

**Killing of Tubercle Bacilli in Milk by Heat.**—W. Rullmann disputes the claims of Storch, Tjaden, and Van Engelen that tubercle bacilli are killed in milk which is heated to 60° C. for twenty minutes and kept in constant motion during this time. Experimentation shows that they are not killed by exposure to 65° C. for thirty minutes under these conditions, since guinea-pigs inoculated with tuberculous milk thus treated regularly developed tuberculosis. The degree of heat and exposure necessary to kill tubercle bacilli under these conditions have not as yet been determined by the author, as his series of experiments is not completed.

**Late Hereditary Syphilis.**—Jordan reports two cases. The first was a soldier twenty-two years of age. His previous history was absolutely good, and it is certain that he had never suffered from any venereal infection. He was suddenly seized at the above age with a bilateral gonitis of the knee-joint. All treatment was entirely without result until anti-syphilitic measures were instituted, when rapid recovery ensued. An examination of the hereditary history showed with certainty that both of the parents were syphilitic. The second case was similar to the above, except that the patient was five years of age and that in addition to the gonitis a keratitis was also present. Both of these cases are interesting because they belong to that rare class in which the *first* manifestations of hereditary syphilis appear after the fifth year of life.

*Berliner klinische Wochenschrift, August* 3, 1903

**Value of the Agglutination Reactions in the Diagnosis of Typhoid Fever.**—R. Stern says that the time has passed when for diagnostic purposes the terms positive and negative Widal reactions should be used, but that such reactions should be designated as specific and non-specific or direct and indirect. Certain sera present in other infections agglutinate the typhoid bacillus as well as other bacilli. Such typhoid agglutinations are non-specific or indirect. Sera which agglutinate the typhoid bacillus *only* are specific or direct. In addition there are certain genuine typhoid sera which agglutinate both typhoid and

other organisms in such cases. When highly diluted these sera fail to agglutinate other organisms but still give a positive result with the typhoid bacillus. Such is not, however, always the case Specific agglutinations are positively diagnostic of typhoid infection while non-specific only give a probability of the same.

**Bovine Inoculation Tuberculosis.**—O. Lassar gives the details concerning two or three cases in which tuberculosis was transmitted directly from infected cattle to men by inoculation. All of the patients were men whose daily avocations required them to come into direct contact with infected cattle. There can be no doubt with respect to the diagnosis, since in every instance portions of the involved tissues were submitted to microscopical examination. These cases when taken in conjunction with similar ones leave no room for doubt that bovine tuberculosis is directly transmissible to man, and that such transmission is not of as infrequent occurrence as has been supposed by some.

*Deutsche medicinische Wochenschrift, July* 30, 1903.

**Treatment of Ankylostomiasis.**—Nagel recommends the use of male fern. Of all the agents which have hitherto been used this is the most deadly to this parasite. If given early and in sufficient dose, accompanied by a purgative, all of the worms are usually killed, and very little if any anæmia develops. Formerly the solid extract of male fern has been the preparation most generally used. Recently the amorphous acid of felix mas has been tried with very satisfactory results. This is given in a single does of 0.7 gm., combined with either chloroform or thymol and castor oil. In place of the latter calomel may be used.

**Thrombosis and Embolism in Acute Perityphlitis.**—Middeldorpf reports a case of acute perityphlitis which was accompanied by embolism of the right femoral artery. Gangrene of the leg resulted. Amputation was performed and recovery ensued. Many cases of combined embolism and appendicitis have been reported, but the peculiarity of this case rests in the fact that the former developed coincidentally with the latter and before an operation for the latter condition could be performed. Furthermore, no other emboli or thrombi ever formed. In these cases the embolism of the femoral artery is undoubtedly due to a thrombosis of the external iliac artery, which arises from a continuation of the inflammation from the appendix.

**Strychnine in Polyuria and Diabetes Insipidus.**—Leopold Peilchenfeld says that the amount of urine may be markedly reduced by hypodermic injections of strychnine. The author first noticed this action of strychnine while using it in a case of paralysis of the bladder. Subsequently he has used it with success in several cases of pure diabetes insipidus. The nitrate of strychnine was used in daily doses of .005 g. The action is rapid, the daily amount of urine being at once reduced from 200 to 400 c.c. None of the cases have been a sufficient time under treatment in order to form an opinion of the permanency of the cure. It is probable that this action of strychnine is due to its influence upon the central nervous system. This is shown by the rapidity of its action and the fact that the specific gravity of the reduced urine remains practically identical with that of the previously increased quantity. If the blood vessels of the kidney were affected by the drug we would expect it to produce a concentrated reduced urine.

*French and Italian Journals.*

**Splenectomy in Banti's Disease.**—Jean Roger states that in Egypt there exists a somewhat common affection which clinically resembles Banti's disease, but which possesses its own characteristics. Splenectomy gives excellent results even when performed at an advanced stage of the disease. To avoid hemorrhage and to expedite the operation, a temporary elastic ligature may be placed on the pedicle. The spleen can then be rapidly removed, and a permanent ligature applied.—*La Presse Médicale*, July 25, 1903.

**A Case of Tuberculosis with Leukæmia.**—Tommaso Prodi reports the case of a man suffering from tuberculosis of the larynx, the lungs and the lymphatic glands, and at the same time from a pronounced lymphatic process. Cases of this kind are rare, and are very generally considered to be mere coincidences. The author, however, holds that there is a true relation between the two processes. Pseudoleukæmia is frequently found in connection with latent tuberculosis, and might be considered to be an intermediate link, especially as cases of pseudoleukæmia have been known to become transformed into leukæmia. —*La Riforma Medica*, July 22, 1903.

**Synovitis of the Sheath of the Abductor Pollicis.**—G. Marion states that there may develop on the external portion of the styloid process of the radius an affection characterized by pain and by a swelling attached to the bone, and as hard as bone. The affection is not an osteitis, but a synovitis situated in the sheath of the abductor pollicis. It can be distinguished from an osteitis by the strict limitation of the swelling, by its elongated form, and by the pain caused by moving the thumb. The synovitis is always a serous form, and is due to exaggerated action of the muscle. Treatment is always efficacious, and consists of revulsion and compression.—*Archives Générales de Médecine*, August 4, 1903.

**Early Diagnosis of Ectopic Pregnancy.**—G. Eustache considers ectopic pregnancy to be of more frequent occurrence than is usually supposed. Its early diagnosis is of the utmost importance and can be based: (1) On the anamnesia, suppression, or delay of one or two menstrual periods, sympathetic affections of early pregnancy, previous uterine disease. (2) Pelvic pain of an acute, paroxysmal nature. (3) Discharges of blood of an atypical nature, not at all resembling the menstrual flow, and causing no amelioration of symptoms. (4) The discovery by internal examination, of a swelling on one side of the uterus distinct at first, but later confounded with the other pelvic organs.—*Journal des Sciences Médicales de Lille*, August 1, 1903.

**Hepatic Fever; Biliary Congestion.**—G. Lemoine gives the treatment of this condition as follows: To evacuate the calculi and overcome constipation, olive oil, and castor oil are indicated. If the fever is high and quinine and the usual antipyretics are contraindicated, calomel will cause defervescence. If the heart is weak, and syncope threatens, give caffeine. Finally local revulsion and the rise of alkalies has often overcome hepatic congestion. When the attack is over, the patient must not be neglected, but means must be taken to prevent resorption of toxic products, and facilitate the excretion of bile. Washed sulphur, in doses of gr. 0.10 to 0.15 a day, or calomel gr. 0.05 a day, are excellent. Podophyllum is also valuable.—*Le Nord Médical*, August 1, 1903.

**The Treatment of Pruritus.**—G. Meillère gives the following general therapeutic formula for pruritus: (1) Local anæsthetics: refrigeration, cocaine, orthoform, menthol, chloral, camphor, phenol, resorcin, sulphophenate, guaiacol, salicylate of methyl. (2) Medicines causing a substitutive reaction: the local anæsthetics given above; alcohol, vinegar, chloroform, tincture of iodine, essence of turpentine, hot and dry air. (3) Antiphlogistics: local vasoconstrictors, cocaine, adrenalin, hot water. (4) Agents affecting the integuments: nitrate of silver, picric acid, tannin. (5) Topical anodynes preserving the skin from irritation: lime and oil liniments, glycerinated lime water, oil, vaselin, lanoline, traumaticin, collodion, and casein ointments. The author also gives a variety of prescriptions for the several kinds of pruritus according to situation and causation.—*La Tribune Médicale*, August 1, 1903.

**Impaired Risks.**—M. Schultess, considering affections of the spinal column in their relation to life insurance, says that round shoulders, simple lordosis, and slight scoliosis are acceptable unconditionally. Paralytic typhosis and lordosis are acceptable conditionally, according to the extent of the paralysis and the degree of the deformity, but only when due to infantile paralysis. Kyphosis, due to spondylitis, is acceptable conditionally, at forty-five to fifty years of age. Spondylitis with ankylosis, grave kyphosis with arthritis deformans, and chronic rheumatism, should be refused. Scoliosis of medium gravity may be accepted conditionally, but not beyond sixty years. Grave scoliosis and kyphoscoliosis are acceptable conditionally only after a favorable examination, at forty and forty-five years.—*Revue Internationale de Thérapie Physique*, August 1, 1903.

**Osteotuberculosis with Extremely Acute Course.**—G. Senni describes a form of tuberculosis which attacks especially the short bones, with possible extension to the long bones. Pain, swelling, and fever are the chief symptoms, and these appear very suddenly, with every appearance of an inflammatory process. Diagnosis is difficult, and frequently operative measures only will decide the nature of the trouble. Another form of acute osteotuberculosis appears to attack chiefly the long bones, especially the femur. The lesion begins in the spongy tissue of the epiphyses, whence it extends to the bone marrow, which it completely destroys, replacing it by fungoid masses and caseous foci. It then attacks the compact substance, which is absorbed until only a thin plate remains, that is easily and spontaneously fractured. The author describes cases of each variety of this rare affection. —*Gazzetta Medica di Roma*, July 15, 1903.

# Book Reviews.

THE AUTOBIOGRAPHY OF A THIEF, Recorded by HUTCHINS HAPGOOD, Author of "The Spirit of the Ghetto," etc. New York: Fox, Duffield & Company, 1903.

THIS evidently true tale of a professional criminal is a human document of great interest alike to the sociologist and to the casual reader. It is the story of the son of honest and God-fearing parents, naturally wild, carelessly brought up, and corrupted by street associates. His thievings were many and varied, from pocket-picking and shop-lifting to burglary. He was convicted of penitentiary offences three times, and was familiar with Sing Sing, Auburn, Matteawan, and Dannemora. Naturally, a criminal would not find much to praise in the management of the prisons in which he was detained, yet with all reasonable reservations of this sort, this story affords convincing proof that all is not as it should be in the management of our penal institutions. The fact that the opium eaters who, constitute a large class among professional criminals, can obtain all the drug they crave from the keepers in Sing Sing or Auburn is evidence sufficient that many of these keepers should be themselves behind the bars. The matter-of-fact allusions to bribery and "grafting" among the police are merely confirmatory of what is generally believed concerning the city's "protectors." The author's reformation appears to have been brought about largely in consequence of his having been cured of the opium habit through forcible abstention at Matteawan, where the keepers were not so corruptible as their colleagues in the penitentiary. So, in spite of what he and others have said of the horrors of these institutions for the criminal insane, they seem sometimes to be productive of good.

URIC ACID AS A FACTOR IN THE CAUSATION OF DISEASE. A contribution to the Pathology of High-Blood-pressure, Headache, Epilepsy, Nervousness, Mental Diseases, Asthma, Hay-fever, Paroxysmal Hæmoglobinuria, Anæmia, Bright's Disease, Diabetes, Gout, Rheumatism, Bronchitis, and other disorders. By ALEXANDER HAIG, M.A., M.D. (Oxon.), F.R.C.P., Physician to the Metropolitan Hospital, and the Royal Hospital for Children and Women, etc. Sixth Edition, Revised. Philadelphia: P. Blakiston's Son & Co., 1903.

IN this large book of nearly a thousand pages the last word is said on the uric-acid theory of disease and its prevention. We should say, perhaps, the latest word, for Dr. Haig seems never through with his discoveries of the uric acid or xanthin content of foodstuffs, and in each new edition of his work he tells of some fresh and hitherto unsuspected source of poisoning of poor humanity. In this edition he sets out for the undoing of Boston and cuts off beans as well as peas and asparagus from the diet of homo sapiens, as he derisively calls his fellow mortals. He is rather down on so-called "health foods" as well, for he finds the universal poison in whole-wheat bread and oatmeal. Eggs have gone by the board long ago, but milk, for some reason, is permitted, although it surely is responsible for the uric acid contained (so we are led to believe) in such undue proportions in veal. The author assures us that, after all his excisions, there is still left a generous bill-of-fare from which we can select our daily food—but frankly, we don't believe him. In addition to these changes, the new edition contains a classification of uric-acid diseases, a record of Haig's work with the uric-acid filter, and some new observations on the state of the circulation as indicative of uric-acid poisoning. One need not go with the author of this book to the extremes of his theory to acknowledge that there is a germ of truth in it, and whether coinciding with his views or not, the reader will find much to interest him in the book, and much also to set him to thinking.

PHYSIOLOGICAL ASPECTS OF THE LIQUOR PROBLEM. Investigations made by and under the direction of W. O. ATWATER, JOHN S. BILLINGS, H. P. BOWDITCH, R. H. CHITTENDEN, and W. H. WELCH, Sub-committee of the Committee of Fifty to Investigate the Liquor Problem. Boston and New York: Houghton, Mifflin & Company.

THIS work is one of a series of reports on various aspects of the Liquor Problem, three of which have been already published. This latest report is preliminary in its nature, and is published in accordance with a vote of the Committee of Fifty passed January 10, 1896. The book which contains ten reports and articles is an important contribution to the literature pertaining to the liquor question. Dr. J. S. Billings, who is the editor, writes of "Data relating to the use of alcoholic drinks among brain-workers in the United States," and on "Relations of drink habits to insanity."

Prof. W. O. Atwater gives his well-known views on the nutritive value of alcohol, while Dr. William H. Welch treats of the pathological effects of alcohol. Opinions of the most distinguished authorities, both in this country and in Europe, have been sought and are incorporated in the work. The sub-committee state that its members are by no means entirely in favor of the manner in which physiological instruction is conducted in many of the public schools in various parts of the United States. Although the growing custom of such teaching in almost all the civilized lands of the world should be productive of much good, yet it is scarcely necessary to impose tasks of this nature upon those who are not sufficiently old to be able to avail themselves of the advantage. The reports edited by Dr. Billings are valuable as sources of reliable information upon one of the most important and pressing matters of the hour.

THE GEOGRAPHY OF DISEASE. By FRANK G. CLEMOW, M.D. Edin., D.P.H. Camb., British Delegate to the Ottoman Board of Health, Physician to H. M. Embassy at Constantinople, Secretary for Russia to the Epidemiological Society of London, Hon. Member of the Russian National Health Society, etc. Cambridge, England: University Press, 1903.

THIS volume, which should prove of much practical use, has been well put together by its author. The facts collected therein have been taken from the best English and European works on the subject, and Dr. Clemow has utilized this material to good advantage. Geography of disease up to the present has been made, but to a small extent, the theme of discussion by writers. This neglect, it seems certain, will be remedied in the future, as the value of reference books of this character must be obvious to all. A commendable feature of the volume under review, is its possession of a considerable number of excellent charts, showing the distribution of the more important diseases to which reference is made

DISEASES AND INJURIES OF THE EYE AND THEIR MEDICAL AND SURGICAL TREATMENT. By GEORGE LAWSON, F.R.C.S., Eng., Surgeon Oculist-in-Ordinary to Her Majesty the Late Queen Victoria; Late Member of the Council of the Royal College of Surgeons of England; Consulting Surgeon to the Royal London Ophthalmic Hospital and to the Middlesex Hospital. Sixth edition, with 246 illustrations. Revised and in great measure rewritten by ARNOLD LAWSON, F.R.C.S., Eng., Assistant Surgeon to the Royal London Ophthalmic Hospital, etc. London: Smith, Elder & Co.; New York: G. P. Putnam & Son, 1903.

THIS edition of the well-known work on diseases and injuries of the eye by Mr. George Lawson constitutes a large volume of 587 pages; the previous issue was published in 1885. The great strides that have been made in ophthalmology since that date have made the increase in volume necessary. The work has been revised, and the attempt has been made to bring it up to date.

The book is well printed on heavy paper, and is quite fully illustrated in black and white. The volume is divided into twenty-seven chapters and an appendix and formulary of remedies are added. Particular attention has been given to special injuries of the eye and their treatment. Foreign bodies within the eye and their localization by means of the *x*-ray, according to the Mackenzie-Davidson method, is fully described. The chapter on affections of the extrinsic ocular muscles is quite extensive and complete, full mention being given of the work of Maddox and to the advances in this line of study made by American ophthalmologists.

The author does not give the consideration to the diseases of the eye, caused by microorganisms, that is accorded to them in modern works by German, French, and American writers; nor are the therapeutic measures advocated fully in keeping with present views. The advice given regarding operations on the eye is conservative and is safe to follow.

The work will be of value to the general practitioner who may desire a book for reference on this subject, but it is not sufficiently up to date to be very serviceable to the ophthalmologist.

HAY-FEVER; Its Prevention and Cure. By PERRY DICKIE, M.D. Pp. 173. Philadelphia: Boericke & Tafel, 1903.

THE author states in his preface that "considering its importance we must admit that the study of this disease has been very much neglected by the medical profession as a body. Actuated by such a condition of affairs, the writer ventures to enter upon this comparatively untrodden path," etc., etc. He then "enters" upon a conventional description of the disease, but gives absolutely no new imformation except to mention a few remedies which homeopathic practitioners claim to have found of service. Absolutely no reference whatever is made to the epoch-marking work of Professor Dunbar, which bids fair to settle once and for all many and probably most of the mooted points in connection with this malady.

MANUEL DE LA PROSTATECTOMIE PÉRINÉALE POUR HYPERTROPHIE. Par le Dr. ROBERT PROUST, Prosecteur à la Faculté de Médecine. Paris: C. Naud, 1903.

THIS excellent brochure is a valuable contribution to the ever-increasing literature concerning the treatment of prostatic obstruction. The author has divided the body of his book into five chapters: No. 1, treating of the surgical anatomy; No. 2, treating of the pathological anatomy; No. 3, treating of the indications for operation; No. 4, on the instrumentation and preparation of the patient; No. 5, on operative technique. In an appendix he gives a report of a few cases. The book is beautifully illustrated, and will be a great help to those who are actively working in this department.

The chapters on the surgical and pathological anatomy are especially commendable. Particularly important is his description of the sheath of the prostate which is to be distinguished from the true capsule of the gland.

The operation which he describes and recommends is done purely by the perineal route. He employs the pre-rectal horseshoe-shaped incision and the consequent careful anatomical dissection which exposes the prostate very satisfactorily, but which, on the other hand, has the disadvantage of prolonging the operation and increasing the loss of blood as compared with the median incision. As an aid to the operation he lays great stress on the extreme elevation of the pelvis, or the posture which he calls the *position périnéale inversée*.

The book is quite comprehensive, and is concisely and well written. It is clearly illustrated, and altogether is a valuable contribution to this subject.

PATOLOGIA E TERAPIA DEL ORECCHIO, E DELLE PRIME VIE AEREE (Otologia, Rinologia, Laringologia). Per il Dottore GIUSEPPE GRADENIGO, Professore nella R. Università di Torino. Torino: S. Lattes & Cia., 1903.

THIS ponderous work consists of thirty-two lectures delivered to practitioners and students by the distinguished Italian professor and is edited by his assistant, Cassanello. It covers practically the entire field of diseases of the nose, throat, and ear, and is arranged on the general principles covering treatises in these special fields. Pathological processes, however, are traced throughout the entire anatomical regions considered instead of being separately discussed under each special division of the work. The latter is profusely illustrated and is above criticism in its general typographical features. Gradenigo has been a frequent contributor to current journals for many years, and this volume sums up his collective clinical experience. He displays a most intimate acquaintance with the general literature of his specialties, and his views are presented from a broad standpoint. A commendable feature is the prefixing to each lecture of a syllabus of its contents

GYNECOLOGY: A TEXTBOOK FOR STUDENTS AND A GUIDE FOR PRACTITIONERS. By WILLIAM R. PRYOR, M.D., Professor of Gynecology in the New York Polyclinic Medical School, etc., etc. One hundred and sixty-three illustrations in the text. New York and London: D. Appleton and Company, 1903.

THIS book mirrors the views and the practice of its author. In style it is direct, forceful, dogmatic. Could it be granted that the views and the practice of an individual were all good and sound, the work *might* claim to be both textbook for student and working guide for practitioner. As it is, whilst the book is honest in its teachings and often sound, in so many respects does its text carry views at variance with those of other teachers that both the student and the practitioner should read and digest many other treatises on gynecology would they avoid lying in and working within a rather narrow groove.

The scheme of the book does not entail consideration of anatomy, embryology, or histology. This is an excellent point, since such topics are best studied in special treatises. The pelvic and the abdominal diseases of woman are, at the outset, studied clinically, and next described from the operative standpoint. The gynecology of the past (that of the tampon, the pessary, and of the intrauterine applicator) rightly is not noticed, neither is there much said about the medical side of gynecology. This is a surgical book, written by a man of strong and positive convictions, equipped by ample experience for the expression of such views. We cannot criticise much that we might from our standpoint and that of many others, owing to the limited space at our disposal. Thus we should be sorry to see adopted the radical views expressed in regard to the desirability of many vaginal operations, or the acceptance of what is termed "Pryor's" operation for adherent retroflexion of the uterus. On the whole, however, we commend the book strongly to all who are ready to study it in conjunction with the writings and the teachings of other men. By this we mean that single-handed it is insufficient for the student and the practitioner who is desirous of becoming a *well-rounded* gynecologist.

The book is well indexed and many of the illustrations are original and creditable.

A REFERENCE HANDBOOK OF THE MEDICAL SCIENCES. By Various Writers. New Edition. Edited by ALBERT H. BUCK, M.D. Volume VI. New York: William Wood & Company, 1903.

THIS enormous volume of over one thousand quarto pages includes all the titles comprised in alphabetical sequence between Moss and Rye. Among the important subjects treated of in most satisfactory completeness are Muscles, anatomy, anomalies, and pathology; Myopia; Nails, diseases; Nasal cavities, anatomy, examination, diseases, neuroses, deformities, new growths, parasites, and sinusitis; Naval hygiene and Naval medical service; Nematoda; Nerves, physiology, histology, trauma, inflammation, functional affections, and pathology; Occupation, hygiene; Œsophagus; Ophthalmoscope; Optometry; Organotherapy; Ovaries; Pancreas, anatomy and physiology, diseases, and surgery of; Paralysis; Parasites; Parotid gland; Pelvis, anatomy and deformities; Pericardium; Perineum; Phagocytosis; Pharynx; Placenta, anatomy and pathology; Pneumonia, in adults and in infants; Poisoning, sources, symptoms, and legal aspects; Prostate; Ptomains; Pulse; Quarantine; Recruits, examination of; Reduction division, interesting in its bearings on the problem of heredity; Reflexes; Reparative surgery; Resection of joints; Petina; Rheumatism; and Röntgen rays in medicine, including the Finsen-light method. In addition to these there are a great number of shorter articles on subjects relating to climatology and balneology to materia medica, both vegetable and mineral, to physiology and pathology, and, in short, to every branch of science relating to medicine. The contributors number 149, there are 764 engravings in the text and nine inset plates in black and colors. There is little to add to what has been already said in notices of the previous volumes of this work. The handbook is to the medical man what any of the great encyclopedias is to the general public, a storehouse of knowledge to which one may turn with confidence for information on any topic relating to his profession. This volume contains subjects of less interest, possibly, than some of those previously issued, but that is the fault of the alphabetical arrangement and not of the editor or the writers—the articles are just as carefully prepared and just as conscientiously treated, and just as instructive to one who seeks instruction on the topics here presented. With two more volumes the work will be completed.

OPHTHALMOLOGY. A Manual of Diseases of the Eye. For Students and General Practitioners. By CLARENCE A. VEASEY, A.M., M.D., Demonstrator of Ophthalmology in Jefferson Medical College, Philadelphia. 12mo. 410 pages, with 194 engravings and 10 full-page colored plates. Philadelphia and New York: Lea Brothers & Co., 1903.

THE author acknowledges his special indebtedness to the eye portion of Miller, McEvoy & Weeks' "Quiz Compend on Diseases of the Eye, Ear, Nose, and Throat;" "some, of the valuable material contained therein has been freely utilized in the preparation of this work." The volume presents, however, better paper, printing, and illustrations than are usually furnished in quiz compends.

As the author remarks in his preface: "It is somewhat difficult in a book of this size to decide what is best to include and the amount of space to be allotted to each subject." This must always be an embarrassment to authors of books of this size, and the success of manuals depends largely upon how cleverly the relative importance of various anomalies is impressed upon the student and general practitioner. The latter depend upon the author for assistance in this direction. We know of a number of Manuals of Diseases of the Eye in which the importance of the various diseases has been much more skilfully emphasized than in the volume before us. Thus, three pages are devoted to a consideration of Tumors and Congenital Anomalies of the Iris—all of which are rare—while only ten pages are given to Iritis, and four and one-half to Sympathetic Irritation and Inflammation. This is a serious handicap to a well-written book.

Some of the illustrations are very good and many are acceptable, as all old friends are. Würdemann's colored illustrations of choroiditis are excellent; but for the class of readers for whom this book is intended, colored representations of conditions of greater interest to students and general practitioners, such as Albuminuric Retinitis and Optic Nerve Atrophy, would have been more consistent and useful. Despite these faults the book is attractive, but can scarcely compete with Nettleship, Swanzy, or May.

### SECTION ON DISEASES OF CHILDREN.

(Continued from page 313.)

*Wednesday, May 6—Second Day.*

**Observations on Prolonged Withdrawal of All Food in the Management of Certain Cases of Intestinal Disorders.**—Dr. THOMAS D. PARKE of Birmingham, Ala., presented this paper. He said that the textbooks did not recommend the withdrawal of food from infants for a period of more than forty-eight hours. The object of his paper was to call attention to the fact that infants might be, with impunity and advantage, deprived of all food except water for a very much longer period. Mention was made of an infant of a few months suffering from ileocolitis and convulsions that had been kept on water and without other food for a period of five days. The stools then becoming of a better character, broths were added. Subsequently a second child, an infant of ten months, was kept for five days upon water, and then egg albumen water was tried, but with an aggravation of all the symptoms. This was accordingly stopped, and after three days more of fasting, the symptoms having improved, diluted food was given, and the child thereafter made a good recovery. An interesting observation was that the child lost flesh only moderately, and that the emaciation was not at all commensurate with preconceived notions of what should occur. Since these two novel experiences, the writer said, he had extended this method of treatment over a period of four seasons. In the majority of cases the withdrawal of food for a few hours was all that was required, but he contended that the cases should be individualized and treated, if the indications were present, by a more prolonged withdrawal of all food. He contended that the character of the stools and the condition of the patient should be the sole indications for a return to food, and not merely the time food had been withdrawn.

Dr. H. M. MCCLANAHAN of Omaha opened the discussion on the foregoing series of papers. He pointed out the meagerness of the literature on normal lactation, and the fact that the majority of medical practitioners did not fully recognize the importance of giving some artificial food when the supply of breast milk was deficient.

Dr. C. G. KERLEY of New York declared that he had never known a woman in any station of life to be unwilling to nurse her infant. Among the wealthy class, where young women were accustomed to a good deal of recreation and indulgence, he made it a practice to allow all nursing infants one bottle a day. One of the commonest errors in the artificial feeding of infants was to give the same food to both sick and well babies. Where it was difficult to make the infant take a sufficient quantity of food, much benefit often resulted from stomach washing. Mothers should be instructed that with the first sign of gastrointestinal derangement to take the child off a milk diet, give it a cathartic, place it on barley water, and seek medical advice. He had seen eight or ten cases of diarrhœa treated with the Shiga serum, and had been favorably impressed with this new treatment.

Dr. R. B. GILBERT of Louisville said that the use of whiskey, and especially of tobacco, by the nursing mother, greatly deteriorated her milk, making it poisonous to the infant. When new-born infants showed a tendency to diarrhœa they should not be allowed to nurse out the colostrum, but the colostrum should be milked out and thrown away. The quality of the breast milk was profoundly influenced by sexual excitement, and, hence, an infant should not be allowed to nurse from the mother for three or four hours after sexual excitement.

Dr. AULD of Chicago said that he had so frequently seen infants of about one year old suffering from convulsions which appeared to have been provoked by milk indigestion, that he was accustomed to stop milk food at this age and put the children on adult food. He had no faith in a child over one year old digesting milk successfully.

Dr. THOMAS S. SOUTHWORTH of New York said that when menstruation caused a temporary disturbance in the nursing infant, it was far better to pump out the breasts during this period and feed the child artificially than to stop breast feeding altogether. It was also well not to be too easily discouraged in our attempts to restore the normal quality of breast milk which seemed to disagree with the nursling.

**Infant Feeding; Its Relation to the Diarrhœal Diseases of Infancy.**—Dr. JAMES G. MASTIN of Chicago read this paper. He said that digestion in infancy occurred almost wholly in the intestine, and that the stomach acted quite as much as a reservoir as an organ of digestion. The young infant was capable of digesting starch and sugar in proportion to the secretory capacity of the pancreas, and starches, sugars, and fats in excess tended to exhaust the secretory function of the glands of digestion by overstimulation. That maternal nursing was superior to any other method of feeding was an established fact, but it must be remembered that mother's milk might not be within the normal limit, even though the woman were in good health. Early and repeated examination of the milk was imperative in order that a proper mode of living might be adopted by the mother. The digestive function of the newborn infant having been once upset, difficulty arose as to the restoration of the normal balance. Our efforts at maintaining maternal nursing were usually successful if carried out properly. When the breast milk was deficient in quantity, one or two supplemental feedings daily were indicated, preferably from a clean spoon. That cow's milk was the best possible substitute for the mother's milk could hardly be denied. The milk should be modified so as to secure the same proportions of fat, proteids, and sugar found in breast milk, this modification including the addition of cereals in order to break up the tough curd of cow's milk. The percentage of proteid should not be greater than one at the beginning. Jacobi has pointed out that cane sugar was preferable to the impure milk sugar of commerce. These observations were intended to apply to the use of "safe" milk, *i. e.* milk containing no pathogenic organisms and not more than 30,000 bacteria to each cubic centimeter. According to Holt, out of 1,943 fatal cases of diarrhœa, only 3 per cent. were fed at the breast exclusively.

Dr. GEORGE W. ACKER of Washington, D. C., continuing the discussion on infant feeding and diarrhœa, said that he could recall many mothers who positively refused to nurse their children. In several instances he had known the wearing of corsets to be responsible for a deficiency in the secretion of milk. Holt had made the statement at one time that only one American woman in ten was able to nurse her child up to the third month, and that it was a curiosity to find an American mother who could nurse after this time. However, it should be remembered that even poor mother's milk was generally better than modified or laboratory milk.

Dr. SOUTHWORTH, speaking of the relation of the Shiga bacillus to infantile diarrhœa, said that he thought it would be found eventually that certain epidemics of intestinal affections in children were due to this bacillus, or to allied forms, and that there still remained a very large proportion of the more acute intestinal affections in which this bacillus was not present. He had seen last winter in hospital a number of cases of infantile diarrhœa associated with the Shiga bacillus. The first symptom was a rise of temperature, and this would be associated with the discharge from the bowel of blood-stained mucus. The stools were not very frequent nor of a very bad character, nevertheless these children would lose several ounces a day, would soon pass into collapse and die within twenty-four hours after the onset of the collapse. The post-mortem examinations showed varying degrees of

enterocolitis, with intense congestion of the lower portion of the intestine.

Dr. H. E. TULEY said that a child was not able to digest as strong a formula of modified milk in hot as in cold weather, and a recognition of this fact would lead to the prevention of considerable sickness.

Dr. A. C. COTTON said that every time even a mouthful of milk in the mother's breast was taken away from the infant an injury was done the little one. He had previously reported about fifty cases of disturbed lactation resulting from excessive coitus.

Dr. DAVIS said she did not wish to be understood as stating that cases in which the breast milk disagreed to such an extent as to necessitate the substitution of artificial food were common; the five cases she had reported in her paper represented an experience of about twelve years with about 1,500 confinements. The early application of the infant to the breast caused the milk to come in more gradually and avoided extreme turgescence of the breasts.

Dr. THOMAS D. PARKE, in closing, said that whenever the baby became sick from indigestion or diarrhœa, he stopped the breast milk just as quickly as he would stop artificial food, and he believed that by this course good results were obtained more quickly and with less risk to the child.

**Case of Probable Gummata of the Liver in a Child of Six.**—Dr. M. OSTHEIMER of Philadelphia presented this paper. The child was a girl whose parents were both syphilitic and alcoholic. On coming under observation there were fever, pain in the side and marked jaundice. The liver was decidedly enlarged, but there was no ascites. The spleen was enlarged. There were no Hutchinson teeth. Protoiodide of mercury and sodium phosphate were given, and this treatment resulted in prompt improvement; nevertheless osteitis developed and tenderness was now at a point midway between the margin of the ribs and the umbilicus. Under mixed treatment all symptoms disappeared in two months. The author then reviewed the literature of the subject.

**Influenza in Children.**—Dr. WILLIAM CARVER WILLIAMS of Chicago read this paper. He said he was of the opinion that influenza was a more malignant disease in children than was generally supposed, and this opinion had been fortified by inquiry among medical acquaintances. It should not be forgotten that the disease was of a remarkably toxic nature, and that the invasion was more insidious than in adults. Dr. F. E. Wynkoop of the Chicago Board of Health had told him that out of 2,460 examinations of cultures from the throats of persons suspected to have diphtheria, 677 showed the Pfeiffer influenza bacillus to be the only pathogenic organism present. Of these 677 cases, in 173 the diagnosis of diphtheria had been definitely made on the clinical findings, and yet no Klebs-Loeffler bacilli were present. Children should not be exposed to the contagion of influenza when other members of the family were known to be suffering from this disease, and they should be carefully guarded against exposures which might lead to catarrhal inflammation and predispose them to infection with influenza. The catarrhal type of influenza was, perhaps, the one most frequently met with in children. The more nearly normal the membranes, the less severe would the disease be if contracted. The nervous, circulatory and febrile types might be regarded as of toxic origin. A variety of the disease receiving little attention was the chronic form. Relapses during convalescence were quite common, and even when the child was apparently restored to health one could not be sure that sequelæ would not develop. The treatment was purely rational and symptomatic, and the indications should be met as they arose. The author's conclusions were: (1) Children of any age were susceptible to the influenza infection; (2) repeated relapses and grave sequelæ were frequent in cases in which the initial seizure was mild; (3) the clinical diagnosis should always be supported by the evidence of the microscope, whenever possible, as the practical certainty thus obtained might be of great value in connection with future developments.

Dr. C. G. KERLEY of New York said that this year he had seen in private practice ten cases of influenza in which it had been necessary to perform paracentesis of the membrana tympani.

Dr. P. J. BARCUS of Crawfordsville, Ind., called attention to the fact that some observers had claimed that when there was an epidemic of scarlet fever prevailing at the same time as one of influenza, the type of the former was unusually mild.

Dr. H. M. MCCLANAHAN of Omaha said that he had noticed that in cases of influenza hydrotherapy failed to control the fever as in other febrile disorders. In his experience there had been more cases of middle-ear disease from grip than from scarlet fever, and the same was true of mastoid abscess. He had been pleased with the results obtained from the administration of quinine by the rectum.

Dr. JOHN C. COOK of Chicago said that he had seen in hospital two babies die suddenly within forty-eight hours of their birth, their mothers being ill with grip. He had seen, during the past winter, four cases of cerebral disorder in which the onset pointed clearly to grip, and in three of these cases at least one of the parents had the grip. He had observed in the recent epidemic of grip several cases characterized by an eruption very closely simulating that of scarlet fever. However, the sore throat and rapid pulse and high fever of scarlet fever were lacking.

Dr. Williams, in closing the discussion, said that he had seen four cases of influenza presenting an eruption, in three of which it closely resembled the rash of scarlet fever.

*Thursday, May 7—Third Day.*

**Capillary Bronchitis.**—Dr. PHILIP F. BARBOUR of Louisvillle presented a paper on this subject. He said that all would agree that in many cases bronchopneumonia was the lesser factor, the real danger to the child being the bronchial element. It was the extent of the bronchitis that was to be feared. The natural tendency was toward extension of the inflammation by continuity of structure. When bronchitis attacked the larger tubes the inflammation was mainly limited to the mucous membrane, and in its extension was usually confined to the mucous layer. As the bronchi became smaller, the histological elements of the bronchial wall became fewer, the non-striated muscular layer became thinner. When the bronchitis extended to the terminal bronchioles, the inflammation no longer involved only the mucous membrane, but also the muscular and fibrous coats. When there was a sudden rise of temperature, and a marked increase in the pulse and respiration rate, the merest tyro knew that there was something more than a bronchitis. When, however, the bronchitis, instead of extending deeply into the air cells, spread widely, dyspnœa and cyanosis developed and became urgent. The danger of capillary bronchitis was that the lungs would be "drowned in their own secretion"—in other words, the danger was mechanical, not febrile as in bronchopneumonia. As a result of the inflammation of the mucous membrane there was marked congestion, and consequently the lumen was diminished. This was still further aggravated by the spasm of the muscular layer. Congestion, spasm, and dryness were the chief elements noted in the early stage, and these factors constituted the main indications for treatment. Hot applications, baths, and revulsives of various kinds were employed. Atropine, by its sedative action on the reflexes, relieved the dyspnœa. The second stage of the disease was characterized by an increase in the secretion, as indicated by a change from the dry, sibilant to the moist râle. The secretion was removable only by deep inspiration or cough, or by rhythmic contractions of the circular fibers in the walls

of the bronchioles. The excessive amount of mucin in the tissues of the child made the secretion of mucus in the tubes relatively greater than in the adult. From this increase of secretion came the chief danger of the second stage. The problem in this stage was how to get air into the lungs, and how to remove the mucus. The latter could be removed by emesis, for which purpose ipecac was probably the best agent. The objection to the irritant emetics was their liability to increase the irritation of the gastric mucosa, which always accompanied this catarrhal condition, and which resulted in part from the swallowing of the mucus. During the coughing or vomiting spells the head should be placed lower than the body in order to get the air of gravity. Much discretion was needed in the use of emetics in order to guard against depression. It should not be practised oftener than two or three times in the twenty-four hours. The expulsion of the mucus would always be favored by any agent which would improve the tone of the muscular coat. Strychnine was best for this purpose, and should be given frequently in small doses and almost to the tetanizing point. Opium acted in an opposite way, and was a most dangerous drug in this disease. Usually after the secretion had been established the mucus was not very viscid, and the chief danger arose from its quantity and the blocking up of the bronchioles with the consequent occurrence of atalectasis. To avoid this, no remedy was equal to atropine or belladonna. There was no objection to the administration of strychnine and atropine at the same time. Aconite had a more desirable action on inflammatory congestion than any other drug, equalizing the circulation and withdrawing the blood from the congested area. Under its use the radial artery was relaxed, and the pulse was made soft. In congestion of the pulmonary tissues aconite would, by its effect on the pulmonary circulation, lessen the amount of blood going to the inflamed area, and thus jugulate the inflammation. Moreover, it prevented the extension of the inflammation along the mucous membrane. The depressing action upon the heart could be obviated by combining it with digitalis, whose antiphlogistic powers had long been known. By using the active principles of these plants greater accuracy of dosage and more effective action would be secured. Under the best treatment the mortality from capillary bronchitis would always be high.

**Management of Catarrhal Pneumonia in Infants and Young Children.**—Dr. CHARLES GILMORE KERLEY of New York presented this paper. He said that this was one of the most formidable ailments the pediatrician was called upon to treat. Among the several hundred cases that had come under his observation not 5 per cent. were primary. It most commonly followed a neglected bronchitis. It occurred with the greatest fatality when associated with diphtheria and measles. Catarrhal pneumonia demanded the best attention possible to give it, not only because of the delicate organ attacked, but because, unlike lobar pneumonia, scarlet fever, diphtheria, and many other diseases of early life, there was no self-limitation or cycle. Every child had a definite resistance to disease, and our effort must be to preserve every strength unit. An immense amount of vitality was wasted in sick children because of irritability, restlessness, and loss of sleep; hence, the first duty was to make the child comfortable, and put it in the best condition to resist disease. We must, therefore, establish a sick-room régime. The value of fresh air was too little appreciated. Direct communication with out-doors was imperative. Perhaps the best and cheapest means of ventilation was the use of a window board, about four inches wide, placed underneath the lower sash, thus bringing the two sashes apart. This insured the entrance of a current of fresh air directed upward, and by pulling down the shade a draught of air upon the patient could be avoided. The temperature of the sick-room in this disease should never register above 70° F. There was a marked tendency to coddle and overclothe pneumonia patients. During the winter children required a medium-weight flannel shirt and the usual night dress. For some years he had discarded the oilsilk jacket because it was cumbersome, could not be kept clean and embarrassed the respiration of the patient. There was but one proper place for the sick infant and that was in a roomy crib. In every febrile disease the digestive capacity was considerably reduced, and if the usual milk diet were continued gastrointestinal disease was very apt to be added to the other disease. The nursing hours should be the same as in health, but the time of nursing should be reduced one-third or one-half. In bottle-fed babies the food should be made half the usual strength. There should be at least one stool in the twenty-four hours. In using medication the efforts of the physician should be to disturb the child as little as possible. If a well child were given syrupy expectorants, stimulants, baths, and other local applications at intervals of an hour or two throughout the twenty-four hours he would have to be a strong child in order not to be made sick. Therefore, the interval between applications and medicines should be made as long as possible, and this could be best done by arranging the régime so that food, medicine, and local applications are attended to at the same time during the night. The author was of the opinion that this was a most important point in the management not only of this but in practically every other disorder of childhood. Among the distinctly remedial measures, steam inhalations with creosote deserved an important place. The patient should be placed in a crib and the latter draped with sheets so as to make a fairly tightly enclosed space. Ten drops of creosote should be added to one quart of water, and this should be boiled in an ordinary croup kettle and the vapor conducted into the crib. This should be done for thirty minutes every three hours, and about once every ten minutes the coverings of the crib should be parted a little to allow of the entrance of fresh air. Steam inhalations for catarrhal pneumonia were so highly thought of by Dr. L. Emmett Holt that in the Babies' Hospital a special room had been constructed in which such patients were placed and connections were made with the system of steam pipes of the hospital. In order that a counter-irritant should be effectual the surface of the skin should be reddened distinctly. The old-fashioned mustard plaster appeared to him to be the most useful in the early stages of bronchopneumonia, or in catarrhal conditions of the chest, although a good revulsive action could be obtained by briskly rubbing the skin with a mixture of oil containing one-third turpentine. The mustard plaster should be made at first of one part mustard and two parts flour moistened with water. After a few minutes it should be removed and the area spread with oil. The mustard plaster should not be used oftener than two or three times in the twenty-four hours, and the physician should map out with a pencil upon the chest just the area to be covered by the mustard plaster. Mustard baths were often very useful in children if given at a temperature of 100° F., and made of the strength of one tablespoonful of mustard to six gallons of water. With regard to medication, the author said that it should be borne in mind that the stomach of a sick child was very easily disturbed. Expectorant drugs must be given with care, and were best prescribed in tablet form, or mixed with water. For a child of one year, $\frac{1}{100}$ of a grain of tartar emetic and $\frac{1}{40}$ of a grain of ipecac answered well when an expectorant was needed. If the cough were very teasing bromide of sodium in small doses might be added. The drugs might be given in powdered form mixed with sugar of milk and water, and two hours after feeding. The ammonia salts were badly borne by the stomach. The muriate of ammonia was of some service, but should not be given in doses of

more than half a grain well diluted, and at an interval of two hours. In those cases in which bathing was not well borne, or was not given intelligently, and the fever ran high, a combination of caffeine and phenacetin at intervals of four to six hours, with a little Dover's powder for great restlessness had been found very useful. For a child of one year old, he would give ⅛ of a grain of caffeine, ½ grain of Dover's powder and ½ grain of phenacetin. When using Dover's powder the effect upon the bowel should be carefully watched. Heart stimulants were commonly used too early, and should certainly not be given unless there was a distinct indication that the heart needed assistance. A heart beating at the rate of 150, not strengthened by sponging or packs, needed assistance, and the drug which had served him best was tincture of strophanthus. It acted as a direct stimulant to the heart muscle, and the heart-beats were made slower and stronger. For a child of one year one drop of strophanthus might be given every three hours. Many physicians were rather timid about pushing the use of strychnine. In many cases of pneumonia it must be given in what seemed to be tremendously large doses, doses which could not be safely employed at other times. It should be given until the desired action on the heart was obtained, or slight physiological effects were developed. Strophanthus and strychnine did their work well, and had no bad effect on the stomach, as was the case with alcohol, digitalis, and ammonia. Alcohol, in the form of whiskey and brandy, was very rarely of service in pneumonia, for, although it would stimulate the heart, this good effect was offset by its disturbing action on the stomach. In some emergencies, when other means failed to meet the indications, it might be given in large doses, half to one drachm well diluted, every two hours to a child one year old. Nitroglycerin, $\frac{1}{100}$ of a grain every three hours, for a child of one year, was useful for marked cyanosis. The one unpleasant effect from its administration that he had observed was the tendency to produce headache. A sponge bath at 90° F. might be given daily for cleansing purposes. If a child were made more comfortable, and slept and ate better when the temperature was reduced, then this should be done. Generally, when the temperature showed a tendency to rise to 104° F. or over it should be reduced. One teaspoonful of salt to a quart of water, or one part of alcohol to four of water, when used as a sponge bath, was most effective, the child being covered with a flannel blanket and sponged under the blanket. The sponging should be continued for ten or fifteen minutes, and then the skin should be rubbed briskly with the hand. If the temperature could not be controlled without very frequent spongings then some other method should be employed. Tub baths had not served him well as an antipyretic. By far the most potent method of controlling the fever was by means of a wet pack. A large bath towel, or any thick material, might be used, and slits should be cut in one end of the towel so that the arms could pass through. The towel should extend from the neck to the middle of the thighs. The arms and the legs, at least from the knees down, should remain free. A hot-water bag, carefully wrapped, should be placed at the feet. The towel should be at first moistened with warm water (95° F.) so as not to cause shock or frighten the child. If the water were made too cold at first it would cause much shock. In a few minutes the towel should be moistened with water at 85° F., and then with water at 80° F. During this time the child should be turned from side to side, but not removed from the pack. The temperature of the water should not be further reduced for half an hour, and then the rectal temperature of the child should be taken. If there was very little or no reduction, and the temperature had been 105° F. at the outset, the water for the pack might be reduced gradually, even as low as 65° or 60° F. The pack could be used in this way even with the child asleep. This pack was very agreeable, so that older children would often ask for the cool water to be renewed. The aim should be to keep the temperature between 102.5 and 103.5° F. He had recently kept a boy of four years, ill with lobar pneumonia, in a wet pack for seventy hours. The towel should be changed for a fresh one twice daily. Oxygen was of great service in very severe cases, given for one or two minutes out of every ten minutes.

Dr. R. B. GILBERT of Louisville said that when an emetic was indicated he preferredt urpeth mineral, because its action was prompt and the subsequent nausea was of short duration.

Dr. THOMAS D. PARKE of Birmingham, Ala., advocated the use of very large doses of strychnine, given by the rectum.

Dr. HUGH A. LEAVELL of Louisville substituted for the usual syrupy mixtures a tablet of antimony and ipecac, $\frac{1}{100}$ of a grain each, when an expectorant was indicated in the early stages.

**The Safranin Reaction in the Urine of Children.**—Dr. W. S. CHRISTOPHER of Chicago presented this paper in abstract, which was read by Dr. A. C. Crofton. This test was comparatively new, but Dr. Christopher had employed it in upward of 3,000 examinations of the urine in children. The test was applied by mixing together and heating 1 c.c. of urine, 5 c.c. of a one per cent. safranin solution and 1 c.c. of caustic soda solution. An exceedingly minute quantity of sugar in the urine would decolorize the safranin solution, but the color would quickly return on slight agitation with air. By an approximate quantitative method what was called "the safranin index" was determined. The following are some of the author's conclusions: (1) Safranin is a reliable and convenient test agent for sugar in the urine, showing sugar when present in quantity much too small to be detected by copper. (2) Safranin is decolorized by sugar but not by uric acid. (3) The safranin index is the number of cubic centimeters of a 1-to-1,000 solution of safranin that are decolorized by 1 c.c. of urine. (4) The normal safranin index is low during the first years of life, but gradually increases, reaching its maximum between the ages of three and four years, after which it slowly decreases for a number of years, but never again becomes so low as in the first year. (5) During the first ten years boys have the safranin index constantly higher than girls. (6) At eleven years the safranin index curves of the two sexes cross, the girl's becoming superior. (7) The curves of urea by ages and sexes closely resemble the corresponding safranin curves. (8) The curves of acidity in disease resemble, in a general way, those of urea and safranin. (9) The safranin and acidity indices vary greatly from day to day. (10) Both the safranin and acid toxæmias play an important rôle in infancy, and are responsible for many of the difficulties in infant feeding. (11) Not less than ten urinary analyses are necessary to determine the safranin index in a child. (12) If the average safranin index is two or more the child may be said to be of the saccharine diathesis. (13) This diathesis was present in about one-third of the children whose urine was examined a sufficient number of times. (14) The management of the saccharine diathesis approaches the management of diabetes. (15) The possibility of diabetes being the outcome of the saccharine diathesis should be borne in mind.

**The Treatment of Scarlet Fever; Its Complications and Sequelæ.**—Dr. H. M. MCCLANAHAN of Omaha presented this paper. He said that for seven years he had adopted the rule of keeping all patients on a liquid diet for not less than four weeks, with the object of preventing renal complications. By a liquid diet he meant milk properly modified to suit the age of the patient. In older children this diet could be modified by adding broths, whey and fruit juices, carbonated water, orangeade, and lemonade. The continuance of the liquid diet not merely for a week

or two but throughout convalescence seemed to him to be the keynote to the treatment. The patient should be kept in bed during this time, thus avoiding the danger of exposing the body to chilling influences by which extra work would be thrown upon the kidneys. Ordinarily if the fever rose to 104° F., it should be controlled, and hydrotherapy was the best means of doing this. A towel wrung out of warm water should be wrapped around the child, and over this a towel wrung out of cool water. Sometimes a full bath was better. The temperature of the bath at the beginning should be about 95°F., and in the course of a few minutes it should be reduced to 80°F. by taking out a quart of warm water and adding a quart of cold water, and repeating this process until the temperature of the water had been reduced to 80°F. in the course of a few minutes. If there were much restlessness it should be controlled by chloral in doses of two or three grains every three or four hours, if need be guarded by digitalis. He favored nasal irrigations with warm saline solution. The child should be wrapped in a towel so as to be completely under the control of the attendant. The first irrigation, at least, should be personally supervised by the physician. The mouth and throat should be first irrigated, and care should be taken to see that during the irrigation of the nose the mouth was kept open. If this were done, deglutition could not well take place, and hence the chief danger of forcing infectious matter into the Eustachian tube would be avoided. He had seen the temperature drop from two to four degrees within an hour after this treatment. When the discharge was fetid he preferred to make use of five grains of potassium permanganate to the pint of warm water. In the septic cases stimulants should always be employed freely. Oily applic ations were useful, not only in hastening desquamation, but particularly in preventing infection of the clothing and room. When the itching was troublesome he made use of a bath of one-per-cent carbolic-acid solution, or, if very severe, of lead water in the strength of one drachm to the pint. Cervical adenitis occurred in all of the septic cases. In such cases he made use of belladonna ointment locally, either with or without ice poultices. Arthritis was a common complication, the elbow and wrists being the joints most commonly involved. For this complication he made use of an ointment composed of sodium salicylate, one drachm to an ounce of a mixture of lanolin and zinc ointment. When otitis complicated scarlet fever it was usually suppurative. Paracentesis was theoretically correct, yet was seldom done in private practice. He favored washing out the ear with hydrogen peroxide to which a little sodium carbonate had been added. If this precaution were taken, and the instillation were made with a medicine dropper he thought there would be no complaint of pain from this application. Stimulating diuretics should be avoided in scarlet fever and laxatives should be used systematically.

**Prolonged or Retained Intubation Tubes, with a Method of Treatment Leading to Their Extraction.**—Dr. B. R. SHURLY of Detroit was the author of this paper. He said that the problem of the avoidance of traumatism was half solved in the selection of a tube of just the right size. Various methods of extraction had been devised, but the O'Dwyer instrument fulfilled all requirements in careful hands. The general rule was to extract all tubes on the fourth day, and a preliminary large dose of diphtheria antitoxin made the success of this method almost certain. If reintubation were required about the sixth day, 1,500 or 2,000 units of antitoxin should be given. In many cases efforts to dispense with the tube at three-day intervals might be made with advantage. Having determined the location of the eroded surface, a 12-per-cent. alum ointment should be applied to this spot, and a string might be left attached to the tube in order to make the extraction as gentle as possible. Tracheotomy was the worst possible thing that could be done, said O'Dwyer, and recent literature from Germany and France confirmed our own methods. The method of direct medication to the larynx in cases of prolonged retention of the tube deserved a more general trial. Adrenalin medication was recommended for cases of œdema. The alum treatment had been successful in practically all of his cases. Cases requiring a tube longer than six days he would classify as prolonged. Rubber tubes only should be used. Large doses of strychnine were of value, and smaller or modified tubes coated with alum ointment or gelatin should be used at each introduction. Tracheotomy was never indicated when intubation could be performed.

**Pseudohydronephrosis or Paranephritic Cyst in a Boy of Three and a Half Years; Operation; Recovery.**—Dr. SAMUEL W. KELLEY of Cleveland was the author of this report, which, in the absence of Dr. Kelley, was read by the secretary. The child had been run over, and while there were no visible signs of injury, the boy appeared to be severely hurt. After a short time it was noticed that the abdomen was swollen. A tumor filled the pancreatic region, but extended back so far that it was thought probable that the tumor was connected with the kidney. There was no pulsation. The growth was evidently cystic. The operation of nephrotomy was done on August 10, 1902, at the Cleveland General Hospital. The pelvis of the kidney was not very large, and contained no calculus or growth that was palpable. The case proved to be one of paranephritic cyst. Gauze and a drainage tube were inserted, and the urine discharged freely around the tube after the operation. The child improved after this operation, and when dismissed with the wound healed he was passing about 24 ounces of urine daily. The fluid in the cyst measured 1,500 c.c., was of a chocolate color, had a specific gravity of 1,013, and was loaded with albumin. No amylolytic ferment was present.

**Officers Elected.**—The following are the officers of the section for the ensuing year: *Chairman*, Dr. Charles G. Kerley of New York; *Secretary*, Dr. Charles F. Wahrer of Fort Madison, Iowa.

## BRITISH MEDICAL ASSOCIATION.

*Seventy-first Annual Meeting, Held at Swansea, July 28, 29, 30, and 31, 1903.*

**Special Report to the Medical Record.**

(Continued from page 318.)

### SECTION OF OBSTETRICS AND GYNECOLOGY.

*Wednesday, July 29—First Day.*

**The President's Address.**—Professor WILLIAM STEPHENSON of Aberdeen gave an introductory address, in which he said that forty years ago the word gynecology was not in use. The younger generation could hardly realise the dread that existed at that time of opening the peritoneal cavity. He well remembered the shock which was given to the professional mind when it was first proposed to use hot water instead of cold for the arrest of uterine hemorrhage. In his earlier days there was a pious dread of interference in cases of obstructed labor and of tumors of the uterus and ovary. A higher standard of medical education was now necessary, that practitioners might be able to know and recognize the gravity of the various conditions, and this was particularly the case in midwifery, because the general practitioner was frequently compelled to be the operator.

The profession has long been conscious that the education of the student in midwifery was unsatisfactory, but the remedy usually proposed, viz., that he should attend more cases, was not the right one, as the number of cases attended was not a criterion of a student's knowledge of the subject, and he (Dr. Stephenson) advocated rather that there should be more oral instruction.

There was at the present day a tendency to separate midwifery from gynecology, but he considered that these subjects could not be divorced. There was a medical and a surgical side of gynecology, but in the textbooks the former was too often overlooked.

A vote of thanks to the president for his address was proposed by Dr. Heywood Smith of London, seconded by Dr. Nelson Jones of Swansea, and carried unanimously.

**The Management of Pregnancy Complicated with Uterine Fibroids.**—Dr. AMAND ROUTH, obstetric physician to the Charing Cross Hospital, London, opened the discussion. He said that in preantiseptic days the mortality of these cases was 50 per cent. for the mother; 60–70 per cent. for the child.

The mortality of cases treated by modern methods had been greatly reduced, and had been given by Pinard as 6 per cent. for the mother; 23 per cent. for the child.

As regards growth during pregnancy, it was universally stated that the fibroids did grow at this time, but C. H. F. Routh and Cullingworth said that they softened, and Whitridge Williams said that the increase in size was due to œdema.

Atrophy during involution did occur in a few cases, but he himself had never seen a fibroid disappear during involution; it was said that this only occurred when lactation was carried out.

Degeneration and necrosis were particularly apt to occur in submucous tumors, and the mass might then be expelled, sometimes without serious symptoms, but usually giving rise to septicæmia.

Infection of the fibroid during the puerperium was common, and if organisms were present even subperitoneal tumors might become infected. Infection was still more common after abortion.

As regards the effect of fibroids on pregnancy, he thought that they were not a common cause of sterility, but that rather the obverse was true, and that sterility caused fibroids. Tubal gestation in association with fibroids was very rare.

As regards the production of malpresentation, statistics showed that in cases of fibroid vertex presentations were 59 per cent. instead of 95 per cent.; transverse presentations were 20 per cent. instead of 4 per cent.; prolapse of funic, 23 per cent.; placenta prævia were 25 per cent. instead of 1 per cent., as regarded obstruction in labor.

Nature's efforts often proved successful in elevating the tumor out of the pelvis after those of the accoucheur had failed. Obstruction depended on position, and was most likely when the fibroids grew from the posterior part of the supravaginal cervix.

*Treatment.*—During pregnancy, replacement should be attempted with patient in knee-chest position, or if necessary an anæsthetic should be given, the foot of the bed being raised. Abortion, which was the treatment thirty years ago, should now be abandoned; the easier it was to induce abortion, the less necessary it was. In absence of urgent symptoms expectant treatment until labor began should be adopted and then the necessary assistance given.

Pain was seldom an indication for operation during pregnancy, and Lewers had shown that though the pain might be severe in the earlier months, it generally improved later in the pregnancy.

If the patient was seen after the child was viable, no attempt should ever be made to drag child past tumor by forceps or version, and if the patient was in labor and we could not replace the tumor, abdominal section was indicated, except in cases of cervical fibroid. Symphyseotomy was quite out of the question. If it was decided at term to do abdominal section, he advised cæsarean section a few days before labor. The following steps might be taken after the cæsarean section, for cæsarean section alone he did not advocate. Sterilization by removing both ovaries with the idea of influencing the growth of the tumor; the speaker did not advocate this.

Myomectomy was advised in the case of young women.

There were three ways of performing this hysterectomy: (1) Porro's operation with extraperitoneal treatment of pedicle; (2) the retro- or subperitoneal operation, and (3) panhysterectomy. He advocated retroperitoneal hysterectomy, and found it simpler in the pregnant than in the non-pregnant state, as it was easier to draw out the tumor and ligate the vessels. The mortality of cæsarean-hysterectomy had dropped from 75 per cent. in 1880 to 20 per cent. at present time.

In cases of septic infection after labor, curetting must not be done, but the uterus may be washed out with strong sodium solution 1 in 4, and if operation required he would do panhysterectomy, as in these cases the more radical the operation the better.

Dr. HEYWOOD SMITH, President British Gynecological Society, discussed the question of marriage in patients with fibroid. He would do his best to discourage a patient with fibroid from marrying.

He thought it best to allow pregnancy to go to term and then to do cæsarean-hysterectomy, and did not advocate myomectomy. He preferred the retroperitoneal method.

Dr. MURDOCH CAMERON of Glasgow thought that in many cases small fibroids, through swelling of surrounding tissues, gave an idea of a big mass during pregnancy. This swelling went down again during involution and gave rise to idea of atrophy.

Dr. HAULTAIN of Edinburgh had no reasonable doubt that fibroids were a potent cause of sterility. Women with fibroids were sterile in 30 per cent of cases. Women without fibroids were sterile in 10 per cent.

Average number of children in women with fibroids, two. In women without, four or five, in the same district. For sloughing after labor he would perform panhysterectomy, even when the fibroid was presenting at the cervix. The presence of fibroids rendered the diagnosis of pregnancy every difficult.

Dr. HORNE of Dublin had seen many cases of fibroids in pregnancy during last few years, and put pregnancy at 1 or 2 per cent. Increase of fibroid during pregnancy depends on œdema; they did not disappear after labor. He narrated a case in which a fibroid appeared certain to obstruct labor, all preparations were made to perform abdominal section; in the meantime labor came on and the tumor was drawn up into the abdomen. He would therefore always wait to see the effect of labor pains before operating.

Dr. J. A. RAWLINGS of Swansea had seen cases of disappearance of fibroid after labor.

Dr. G. WATTS EDEN of London said that, judging from his own experience, he should not on the whole regard fibroids as a serious complication of labor; he had seen many cases even with quite large fibroids go safely through labor; he would hesitate to advise a woman with a fibroid not to marry. He entirely disapproved of interference during pregnancy, especially of inducing abortion. He would like to have the term "pressure symptoms" defined; he would not allow that frequent micturition and pain were pressure symptoms. He was entirely in favor of leaving cases until labor had been some time in progress.

Dr. HELME of Manchester believed that there was hypertrophy of fibroid along with general hypertrophy of uterus during pregnancy. He always removed both ovaries.

Dr. EDGE of Wolverhampton performed panhysterectomy, as cases of supravaginal hysterectomy had been reported in which the cervix had sloughed after the operation, as a result of arrest of its insulation by the ligatures.

Dr. LAMOUX SACKIE of Edinburgh had seen a case in which the tumor underwent natural replacement during labor, but returned, and would not be pushed up when chloroform was given, to extract the placenta.

Dr. Routh, in reply, said there was no object in tying tube to induce sterility in these cases; better to remove ovaries and so have good effect on fibroid. He had never seen disease develop in ovaries which had been left, nor

cancer attacking the cervix which had been left after panhysterectomy.

The operation was easier to perform at full term than earlier in pregnancy.

Dr. PURSLOW of Birmingham then read a paper "On a Case of Persistence of the Urogenital Sinus, with Especial Reference to the Later Theories of the Mode of Development of the Female Genital Tract."

*Thursday, July 30—Second Day.*

**The Diagnosis and Treatment of Uterine Fibroids.**—Prof. MURDOCH CAMERON of Glasgow read a paper on this subject. He looked upon sterility as a result rather than a cause of fibroids. He drew attention to a point noted by himself that a fibroid growing from the fundus had frequently a "bullock's heart shape."

He did not believe in disappearance of fibroids at the menopause. In some soft cystic fibroids there were breast changes rendering the diagnosis from pregnancy difficult. There was usually marked hypertrophy of the ovaries.

*Treatment.*—When causing no symptoms delay was advisable. Hysterectomy was the most satisfactory way of dealing with these tumors. Enucleation and oophorectomy had been generally abandoned.

Dr. HEYWARD SMITH of London thought enucleation sometimes a very good treatment even when there was a broad attachment of the tumor, but we should follow Marion Sims's advice, and when once enucleation was commenced always complete it.

Dr. MACLEAN of Cardiff had found rhythmical contractions present in a fibrocystic tumor.

Dr. J. J. MACAN of London raised the question of the removal of the tumor in some cases for esthetic reasons.

The PRESIDENT considered that operation in fibroids was not justified unless there was a distinct warning of danger to life. He had watched cases for thirty to forty years, and they had not developed any dangerous symptoms.

**A Clinical Study of Internal Hemorrhage in Association with Ectopic Pregnancy.**—Dr. JAMES OLIVER of London read this paper. He thought that the hemorrhage in the early days of tubal gestation did not come from the wall of the tube, which was in contact with the ovum, but from that on each side.

Hemorrhage in uterine gestation was rare before six weeks, but in tubal might begin from the earliest days. The blood finds its way to the peritoneal cavity or the uterus. Tait laid stress on previous history of tubal disease, but his own experience was opposed to this. Pain was usually the first symptom, and there was faintness even when the amount of blood extravasated into the peritoneal cavity was small. Sometimes the appearance of vaginal hemorrhage was the first symptom. In most cases there was preceding amenorrhœa. Decidual membrane was not as common as most authors state. Occasionally micturition was difficult, or there was even retention of urine, but the latter could not always be put down to pressure. Rupture occurred between the sixth and twelfth week, and there might be no physical signs in the pelvis, but marked collapse.

In broad ligament hæmatocele much blood may be effused, as the broad ligament is readily distensible, and a large tumor may result. The mobility of the uterus was affected and an annular constriction of the rectum might be detected, especially when the blood was in the left broad ligament. Hæmatoma in the peritoneal cavity gave rise to a peculiar characteristic doughy sensation to the fingers.

Dr. HORNE of Dublin, vice-president of the section, agreed with Tait's theory of previous sterility.

Dr. KIDD of Dublin thought one cause of ectopic gestation was some inflammatory reaction which had damaged the lining membrane of the tube.

Dr. PURSLOW of Birmingham drew attention to the error of mistaking a tubal gestation for uterine abortion, into which we were likely to fall, and of which he had seen two instances, and said that the severity of the pain and the occurrence of faintness in a case of supposed uterine abortion should make one suspicious that the diagnosis was incorrect.

Dr. T. WATTS EDEN of London said that one after another the explanations which had been given of ectopic gestation had had to be given up. No sign of previous salpyngitis had been found, on careful pathological and microscopical examination, and the tube away from the attachment of the ovum had been found to be perfectly healthy. It had been proved that an ovum in the tube actually penetrated the muscular wall, and this was not the case with an ovum in utero.

Anatomists said that there was a decidual formation in the uterus in every case, but he agreed that the membrane was not always discharged. He thought that the vaginal hemorrhage in these cases came from the uterus and not from the tube. He had met with difficulty in the diagnosis from intrauterine abortion. He thought that cases of extreme fatal bleeding were rare.

Dr. GRIMSDALE of Liverpool said that the majority of his cases had been young newly married women. The most frequent mistake in diagnosis was in connection with uterine abortion. Among the causes he would place congenital malformation in the tubes, such as diverticula.

The President pointed out that the amount of collapse was not proportionate to the extent of the hemorrhage, and that the pulse must be our main guide in deciding the question of operation.

**Cæsarean Section in Dwarfs.**—Dr. MACLEAN of Cardiff reported two successful cases of cæsarean section for contracted pelvis in dwarfs. The patients were sterilized by removing one inch of each Fallopian tube. Both mothers and children recovered.

Dr. OLIPHANT NICHOLSON of Edinburgh read a paper entitled "Some Remarks on the Maternal Circulation in Pregnancy."

*Friday, July 31—Third Day.*

**The Diagnosis and Treatment of Tuberculosis of the Uterus and Adnexa.**—Mr. J. H. TARGETT of Guy's Hospital, London, opened this discussion. He said it was not until 1886 that attention was first drawn to this subject by Hegan. In 1894 a complete account was given by Whitridge Williams, and last year at the congress of gynecologists in Rome the subject was fully discussed. The post-mortem records of the Brompton Hospital for Consumption showed that 6 per cent. of tuberculous females showed disease in the genital organs, but the number of cases in which the disease was primary and limited to the genital organs was much smaller.

The modes of infection were: (1) By the blood stream, the first infection taking place in the lymphatic glands, usually the bronchial, and being carried from there by the blood stream. The tubes were readily infected. (2) From the peritoneum there were three ways in which this occurred: (*a*) From general miliary tuberculosis; from localized disease due to ulceration of bowel. (*b*) From fluids in the peritoneal cavity conveying infection through the abdominal ostium, Tuberculous salpyngitis was found in 50 per cent. of cases of tuberculous peritonitis. (3) Infection from neighboring organs, as the rectum, ileum, or bladder. (4) (*c*) From sexual intercourse; it could not be denied that this occurred, but it was very rare. Tuberculosis of the glans penis was excessively rare, and the infection must occur through the semen.

The Fallopian tubes were involved in 90 per cent. of cases of genital tuberculosis, and the ampullary portion was most often attacked. The disease might take the form of acute tuberculous salpyngitis, caseous salpyngitis, or tuberculous pyosalpynx; the latter presented some special peculiarities; these were absence of adhesions, persistence of the fimbriæ, these not being turned in and obliterated as in ordinary salpyngitis. The contents were

honey-like and frequently sterile bacteriologically. Tuberculosis of the uterus in the majority of cases spread from the tubes.

*Symptoms and Diagnosis.*—It was formerly taught that amenorrhœa was usual, but further experience has shown that is not so. Dysmenorrhœa was usually present. As regarded pelvic pain, he thought that it was not a prominent symptom, unless other organisms were present in addition to the tubercle bacillus. Large pyosalpynx, without pain, especially without recurrent attacks of pain, was generally tuberculous. When tuberculosis affected the body of the uterus it was seldom that there were bacilli in the discharge; he had examined microscopically about 1,000 specimens from uterine curettings and in only seven cases had he found the tubercle bacillus. The previous history was of great importance. The absence of an apparent cause was also important, thus pyosalpynx in a virgin was almost invariably tuberculous in origin.

*Treatment.*—Laparotomy was very beneficial. In some cases pus might be evacuated by a vaginal incision. If thickened tubes were found during a laparotomy for tuberculous peritonitis they should be removed. He had seen a rapidly fatal termination of cases in which caseous, strongly adherent tubes had been removed, and he questioned the wisdom of interference when this condition was found. There was no doubt as to the advisability of removing tuberculous pyosalpynx.

Mr. Targett then gave a lantern demonstration of eighteen most excellent photographs of specimens in illustration of the subject

**Primary Tuberculosis of the Uterus (Cervix).**—Dr. HYNOCH of Dundee, followed with a paper on this subject. He distinguished three forms—ulcerative, miliary, and papillary. The latter extended on to the vaginal portion, but the growth was not friable, though it bled freely on examination. There was menorrhagia in the early cases, amenorrhea in the later. The treatment was by hysterectomy. Curetting was not sufficient on account of the possibility of the uterus being affected.

**Tuberculosis of the Fallopian Tube.**—Dr. ARNOLD LEA of Manchester reported five cases of tuberculous disease of the fallopian tube treated by operation. He said that the diagnosis of the parts removed should never be made without a microscopical examination, as nodules, exactly resembling tubercle, were found in the tube in other conditions. In two of his cases no other part of the body was affected; in only one was there tubercle in the ovary. The symptoms were pain, which was a marked feature in each case. There was usually previous sterility. The previous history, especially of tuberculous lesions elsewhere was important. Evening rise of temperature was generally found.

*Technique of Operation.*—Ligature of the uterus, cornu first, then ligature in sections across the broad ligament. Drainage, if used, should be vaginal.

Dr. HAULTAIN of Edinburgh said that dysmenorrhea was the most constant symptom. He narrated a case of tuberculous disease of cervix in which there was a soft growth of peculiarly blue color on the cervix; this was removed by supravaginal amputation, and under the microscope proved to be tuberculous.

Dr. MACLEAN of Cardiff narrated a case of which the symptoms were obscure pelvic pain for four months; dyspareunia; definite fixed pain referred to the umbilical region; menorrhagia, leucorrhea, and swelling in Douglas's pouch. The left tuberculous tube was removed. The speaker thought operation was always advisable.

Dr. STRATON of Salisbury narrated a case of sexual infection. The husband had tuberculous disease of the kidney. The wife developed a growth on the cervix and vaginal wall which, on microscopical examination, was pronounced to be tuberculous.

Dr. TARGETT, in reply, said that *x*-ray treatment was not likely to be of any service because, in all cases of disease of cervix, nodules were found situated deeply in the tissues; it was doubtful if the pure tubercle bacillus was a pyogenic organism, and when pus was present he would suspect that other microorganisms were also present.

**Hairpin in the Uterus.**—Dr. A. H. N. LEWERS of London reported a case of hairpin in the uterus discovered by *x*-rays. The patient came to hospital saying that she had pushed up a hairpin in order to "open an abscess" and it had slipped from her grasp. Examination by finger and sounding of uterus and bladder failed to reveal the pin. The radiograph showed the pin in uterus, points downward. The patient was anæsthetized and the cervix was dilated with Hegar's dilators. Each point of the hairpin was seized by Spencer Wells' forceps and the pin was thus removed. A piece of the placental tissue was also found in uterus and removed. A severe septic attack followed the operation, with suppuration in the pelvis and thigh, necessitating incisions, but the patient eventually recovered.

Negebauer had collected seventy-four cases of foreign body in uterus, and in sixteen of those the foreign body was a hairpin. This was the first recorded case in which the diagnosis had been made by the *x*-rays.

**A Vote of Thanks** to the president, proposed by Dr. Heywood Smith, and seconded by Dr. J. J. Macan, terminated the proceedings.

### SECTION OF SURGERY.

*Wednesday, July 29—First Day.*

THIS section was presided over by Mr. Edmund Owen of St. Mary's Hospital.

**Intraabdominal Anastomosis.**—Mr. G. H. MAKINS opened the discussion with a paper detailing his experience regarding the most satisfactory methods of operating. As regarded the safest and generally preferable variety of anastomosis, he held that axial or end-to-end union gave the ideal result from both a physiological and a cosmetic point of view. There was only one line of suture with a corresponding limitation of area of possible leakage, but there was the drawback that nutrition was more interfered with. Lateral anastomosis might be called the natural method, the plane peritoneal surfaces being brought together, and the size of the communication being at the command of the operator. There was no danger of a diaphragm formation, and the anastomosis might be made at a distance from the field of operation. Three lines of sutures were needed, and there was some risk of leakage, though slight, from the closed ends. The third form of anastomosis was by lateral implantation. In this there was no risk of diaphragm formation, and only two lines of sutures were required. The method was, however, suitable only for uniting portions of great difference in lumen.

The comparative results of axial and lateral union were then reviewed. The statistics of St. Thomas's Hospital showed a mortality of 53 per cent. following axial anastomosis performed for all causes; but Littlewood, in eleven enterectomies for carcinoma of large bowel had only 27.27 per cent. mortality and one stitch failure. Von Eiselsberg had twelve resections for intussusception followed by axial anastomosis ileocolostomy, with 25 per cent. mortality.

Lateral anastomosis was safer than axial and more suitable for the large intestine. Recent statistics from St. Thomas's showed 30.7 mortality. Schloffer did ileocolostomy ten times, with a mortality of 30 per cent. Ileocolostomy with resection eighteen cases, with 44 per cent. mortality. Roskoschny, thirty-four short-circuit operations, 20.5 per cent. mortality. St. Thomas's Hospital resections for carcinoma of large bowel twenty, axial twelve, with 50 per cent. mortality and five fecal fistulæ, eight lateral unions with 25 per cent. mortality. Fuchsig,

sixteen lateral anastomoses with 37.5 per cent. mortality, twenty-four axial unions with 54.16 per cent. mortality.

In gastroenterostomy the general mortality from all causes did not exceed 30 to 40 per cent., and stitch failures were much fewer; thus Schloffer, in seventy cases, had no stitch failure; at St. Thomas's Hospital, in forty-two cases, there were two stitch failures. Mayo Robson had 103 cases with no stitch failure.

Mr. Makins then proceeded to consider various points affecting all methods of operating. These had to do with the preservation of the wound from infection, the importance of which was obvious. Careful clamping on each side of the field of operation was necessary. He preferred clamps to digital compression. He considered Doyen's the best form of clamp yet devised. The amount of mesentery to be removed depended on the cause of the operation. Thus gangrene of bowel determined the amount of mesentery. But if a new growth had to be excised the amount of intestine to be removed was determined by the extent of disease of the mesentery. In order to avoid hemorrhage it was advisable to remove the mesentery before opening the intestine. This was also best in order to prevent septic infection. Folding of the mesentery, so often done, was not altogether safe. Septic thrombosis might be present. Two tiers of sutures were necessary. He preferred simple continuous sutures. The simpler the method the better; and though Murphy's button was good in theory, there were grave practical disadvantages to be weighed.

Mr. Stanmore Bishop of Manchester followed with a paper founded on a study of twenty-two cases of intestinal anastomosis, most of the operations being undertaken on account of hernia. One case proved fatal through the formation of a diaphragm which became œdematous and caused obstruction. Some gangrenous bowel had been removed and the ends united by a Czerny-Lembert suture. He thought absorbable appliances were suitable only in the upper part of the canal where the liquid contents could act upon them. In the large intestine the condition was different and there could be little or no digestive or solvent action. Mr. Bishop showed a number of appliances and commented upon their relative merits. He spoke favorably of some dough bobbins used by Wackerhagen, as they were easily dissolved; also of Frank's "bone couplers." He described a number of other mechanical supports—O'Hare's, Vidal's, Doyen's, and others. He questioned if a mucous-membrane suture prevented the formation of a diaphragm, and thought the danger of the sutures perforating all the coats of the intestine had been exaggerated. The object of suturing was to get a firm hold of the submucous coat. The dangerous suture was that which yielded because it had not a good hold on the tissues. Mr. Bishop's paper was illustrated by a series of important specimens and a number of diagrams.

Mr. Jordan Lloyd of Birmingham then addressed the section, advocating above everything simplicity of procedure. He employed common sewing needles with ordinary silk, which he, of course, sterilized. Many of the mechanical appliances which had been used added to the risks of the operation. Murphy's button was not simple in application and did not save much time over simple suture. Hemorrhage was the chief danger, and he thought lateral anastomosis as the safest plan should be preferred when possible. He considered the abdominal wound should be large enough to permit easy manipulation.

Mr. Deanesly of Wolverhampton took exception to the statement that lateral anastomosis was a natural method; on the contrary he thought the axial was more natural and he preferred it. In support of this he remarked that in cases of intussusception, when sloughing of the intestine had occurred and subsequently union had led to recovery, it was end-to-end union that had taken place. He employed two tiers of sutures, passing the first through both coats. Accurate suturing was more important than any method. Good silk and needles were the only appliances necessary. He passed each row as a complete, uninterrupted suture. A diaphragm would form in every case, but it would not be large enough to impede action provided too much bowel was not turned in.

Mr. Elsworth of Swansea said he had recently performed anastomosis in six cases. He had used Murphy's button in all, and they had all recovered. He added a few external stitches in support. He thought most of the fatalities in connection with the button were due to defective technique. The parts of the button must be well pressed together.

Mr. Basil Hall of Bradford formerly used the bone bobbin, but had now abandoned it in favor of simple sutures. He used catgut for the inner one, which he had no hesitation in passing through all the coats of the bowel. For the outer he used silk.

Mr. G. G. Hamilton of Liverpool had also given up the button for simple sutures. He had formerly used Murphy's button in two colectomies, and he thought it more adapted for the large than the small intestine. Both patients recovered.

Mr. Sinclair White of Sheffield advocated lateral anastomosis as safer, he thought, than any other plan, and therefore to be preferred when practicable, but admitted it was not in all situations the method of choice. He had operated many times with Murphy's button, but he now used simple suturing. In five cases he never saw the button again after the operation.

Mr. Mitchell of Belfast was greatly in favor of two tiers of sutures, the inner one passing through all the coats, the outer one through the serous muscular and submucous layers. In lateral implantation he made the incision into the intestine transverse, to be parallel with the vessels.

Mr. Mayo Robson was much in favor of sutures, but he thought his bobbin was useful as a support. Murphy's button he considered harmful, for the surgeon could never tell what might happen with it. The bobbin gave a continuous channel, protected the line of sutures as a splint and prevented subsequent contraction.

Mr. Horrocks of Bradford related a case in which he had excised thirty-six inches of intestine for malignant disease. He invaginated the lower into the upper portion and fixed them in place with sutures. The case did well, and he thought that gangrenous bowel might sometimes be invaginated to a considerable extent without undue risk.

Mr. F. Burghard thought hemorrhage was best prevented by continuous sutures passing through all the coats. As to the material of which the sutures were made, he regarded that as a minor point. The diaphragm which sometimes formed after axial anastomosis was evidently caused by too much bowel being turned in.

Mr. Owen, president of the section, expressed much satisfaction with the interesting discussion. He thought the best clamp was the fingers of a good assistant; the next best a thin rubber tubing, not too tightly tied. He was surprised no one had referred to the triangular gap in the mesentery, which he thought should be carefully sewn up.

### SECTION OF SURGERY.

*Thursday, July 30—Second Day.*

**Advanced Tuberculosis of the Knee.**—Less interest was exhibited in the second day's discussion, which was on advanced tuberculous disease of the knee-joint. By the term "advanced" it was intended to indicate that stage in which some sort of operative interference becomes necessary.

Messrs. G. A. Wright and W. F. Haslam of Manchester opened the discussion. Their paper was founded on replies to questions sent to nearly two hundred hospital surgeons. Only seventy-five had answered the

questions at the date of the meeting. Among them were many differences of opinion. The majority put progressive disease and suppuration as the chief indications for surgical interference. Erasion was generally considered the best procedure in the young, but in adults excision was thought preferable by about half those replying. The ordinary horseshoe-shaped incision was mostly recommended, retaining the patella, and when practicable, the crucial ligaments. The diseased bone was scooped away by most, and some applied antiseptics afterward. An elastic tourniquet was generally used, but removed for the dressing.

Opinions in regard to drainage seemed pretty equally divided. Thomas's splint was favored by most, and the majority also agreed that no attempt should be made to obtain a mobile joint.

Having thus summarized the replies to questions, Mr. Wright went on to state his own practice. He operated if there were no improvement after three months' treatment, or if there were evidence of caseation, but if the disease was very far advanced he thought neither excision nor erasion should be performed. He made a transverse patellar incision, divided and wired the bone, left the crucial ligaments whenever possible, scooped out diseased bone, and did not drain except in septic cases. He used an elastic tourniquet without an Esmarch bandage, and took it off before he applied any dressing. He used Thomas's splint for two years after operation, but seldom tried to get a movable joint after operation. Now and then, but not often, shortening occurred after erasion, which he thought a very satisfactory operation if thoroughly done. He first did it in 1881 and had had many successes. Failure, he thought, was generally due to infection. He was of the opinion that in most cases the disease began in the synovial membrane.

Dr. Ward Cousins thought the disease began as often in the bone as in the synovial membrane. He believed in erasion for children. He had excised the joint in patients from fourteen to fifty-two years of age. He removed only a thin layer of bone and scooped out any deeper patches and applied a bracketed back-splint. He had not had to amputate in more than 2 per cent. of all his cases.

Mr. Keetley said the word erasion was a misnomer. The diseased tissue had to be cut out, not scraped. The great point was to remove it all and secure rapid healing, to prevent recurrence.

Mr. Tubby thought the ankylosis obtained was seldom bony.

Mr. Monsarrat had had ten erasions. Nine were now well; the other had to be amputated.

Mr. Sinclair White performed excision early in hospital cases, as they mostly came to that in the end.

Mr. Beetham Robinson thought amputation best in hospital cases if caseous foci were present.

Mr. Mitchell recommended early operation and said faulty application of Thomas's splint often was the cause of after-flexion.

Dr. Latimer of Swansea preferred excision, as it was often impracticable to remove all diseased bone with a gouge.

Dr. Ferguson of Cheltenham performed excision in adults, applied antiseptics and wired the bones.

Mr. Edmund Owen recommended amputation and considered the best result of excision to be only a miserable condition when any bone was removed, a movable joint was not to be expected and a stiff leg was always in the way.

Mr. Jordan Lloyd demurred to this and thought a man's own leg was better than an artificial one.

Mr. Wright in reply remarked that some of the speakers seemed to confuse erasion and excision, but the distinction was important, for excision always interfered with the growth of the bone.

**Gastrojejunostomy.**—Mr. Basil Hall read an account of a new route for posterior gastrojejunostomy. He published reports of four cases last year and had had eight since.

**Gastroenterostomy.**—Mr. Eccles then read a paper on a danger of gastroenterostomy. In the case related there were many adhesions about the pylorus. The patient died of hemorrhage on the fourteenth day. At the autopsy a deep ulcer was found just beyond the pylorus. It had eaten through the wall of the bowel and perforated the hepatic artery. He thought perhaps the manipulation had caused a fresh extension of the ulcer.

*Friday, July 31—Third Day*

**Operative Treatment of Ascites.**—Mr. Sheen of Cardiff read a paper on a case of cirrhosis of the liver and ascites successfully treated by operation. He said he believed that the beneficial result was more due to the prolonged drainage than to the foundation of adhesions, as was supposed to be the case by the originators of the operation. Other speakers referred to cases within their knowledge.

**Prostatectomy.**—Dr. P. J. Freyer read a paper on this subject and showed many specimens. The larger the prostate, he said, the easier was its removal. The "record" in celerity of operation was two minutes from the time of taking the knife in hand until the prostate was on the table. He was now able to deal with smaller prostates than formerly. Much interest was taken in the appearance on the platform of a gentleman, obviously in the best of health and spirits, who described himself as the proprietor of one of the glands on the table. He described his former suffering and their relief by Mr. Freyer, and said he would challenge any member of the association to empty his bladder quicker than he could. With a jaunty step this speaker tripped nimbly down the ladder from the platform among a round of applause and laughter.

Mr. Reginald Harrison of London said that he preferred the perineal route to the suprapubic.

Mr. Jordan Lloyd and other speakers took part in the discussion.

**Epiphyseal Separation.**—Mr. Betham Robinson described two cases of separation of the upper or acetabular epiphysis of the thigh bone in young men. The diagnosis of this injury, he said, was difficult and *x*-rays were of great use. It occurred generally in adolescents and was probably preceded by some change in the cartilage akin to rickets. In children, fracture of the neck was more likely to happen. He referred to the valuable work of Royal Whitman on the subject.

**Phelps' Operation for Club-foot.**—Mr. Muirhead Little read a paper on this subject. The untimely death of Dr. A. M. Phelps, he said, was a loss to surgery in general, and to orthopedic surgery in particular. He said he believed that the low opinion held of the operation in this country was apparently due to a want of attention to the immediate after-treatment. He had had no relapses in his cases and never a complaint of pain on the scar or elsewhere. He had lately adopted a method of treatment by reflecting a flap of skin, which hastened healing and was, he thought, a great improvement and did away with the unsightly scar, but if this method were followed it was more than ever necessary to keep the foot well stretched during healing. He showed photographs of late results from fifteen months to ten and a half years after operation.

Mr. A. H. Tubby described these results as excellent.

---

**Deaths from Plague in the Punjab.**—It was stated a short time ago, in the British House of Commons, that the deaths from plague in the Punjab district of India, from January 1 to May 2, numbered 141,789.

# Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 22, 1903;

| | Cases. | Deaths. |
|---|---|---|
| Measles | 117 | 3 |
| Diphtheria and croup | 296 | 24 |
| Scarlet fever | 104 | 4 |
| Smallpox | ... | ... |
| Varicella | 12 | ... |
| Tuberculosis | 271 | 141 |
| Typhoid fever | 109 | 19 |
| Cerebrospinal meningitis | ... | 6 |

**Other Sources of Typhoid Infection than through the Mediumof Drinking Water.**—Seale Harris mentions the following causes, milk, flies, dust, contact infection, uncooked vegetables, oysters, and ice. Dairies which supply milk to cities should be regularly inspected; cows should not be pastured in lowlands upon which the sewage of small towns are drained. Flies present a great problem. Something may be done to destroy flies in their breeding places, which is largely in the excreta from horses, and in human excrement. Chloride of lime will destroy the larvæ. Human excreta used as a fertilizing agent may carry infection. Vegetables should be thoroughly washed in pure water. Ice should be made only of pure water. Finally the prevention of typhoid fever should begin by limiting the infection to the patient under treatment.—*The Mobile Medical and Surgical Journal.*

**Physical Signs of Arteriosclerosis.**—Charles Louis Mix says that arterial conditions are responsible for a larger number of deaths than is ordinarily supposed, on account of their effects upon kidney, heart, and brain, and no physical examination is complete which neglects their consideration. The author gives the methods of diagnosis of the condition. The physical signs of hypertrophy of the heart consist first in an increase in the area of dulness, secondly, an accentuated second aortic sound, and also second pulmonic sound provided the right ventricle is hypertrophied. Arteriosclerosis of the brain cannot, as a rule, be demonstrated by ordinary physical examination. In arteriosclerosis of the kidneys, cardiac hypertrophy sets in earlier, and long before the kidney lesion betrays itself; albumin is less likely to be present, and only after a long period of preceding polyuria; the albuminuria is likely to be transitory; the specific gravity to be higher than in the primary form, and the polyuria less pronounced; the secondary disturbances of kidney and brain are likely to be of rapid course, because of the early evolvement and laming of the arteries and heart.—*The Medical Examiner and Practitioner.*

**Some Remarks on Corsets.**—W. E. Frothingill says that the modern woman wears heavy skirts the weight of which is supported by bands around her waist—that soft portion of the body which is protected by no body walls. How is it possible to wear around this portion of the body bands which support the weight of numerous and often heavy garments? The answer is, by means of the corset. The garment forms a bridge connecting the firm chest wall with the firm pelvis. The use of the corset is to transmit the pressure of the skirt-bands to the hips and the ribs, and so to protect from their pressure the organs in the region of the waist. The conclusion is, that so long as skirt-bands are fastened round the waist, corsets should be worn. They should be stiffer than usually made if they are effectively to protect the soft, middle portion of the body from the pressure of the waistband. The front should be quite straight, and the waist measurement should be at least as large as the wearer's waist, measured over a single, soft garment. The abuse of the article consists in employing it as a means of compressing that which it was meant to protect from compressing, namely, the soft, middle portion of the body. Fashion in corsets has of late made a motion in the right direction, in the straight, stiff front.—*Medical Press and Circular.*

**Note on the Vital and Toxic Theories of Cancer and Their Bearing on the Parasitic Theory.**—G. H. A. Clowes holds that the parasitic theory of the origin of cancer is not in any sesnien compatible with the various toxic or chemical theories; in fact, that the production of the toxins generally recognized as playing an important part in this disease, may most readily be attributed to the introduction of some form of intracellular parasite which, on infecting the cell, proliferates, produces toxins, and then indirectly stimulates the host cell to proliferation. This theory suggests an explanation for: (1) The production in ever-increasing quantities of some body capable of stimulating the cancer cell to enormous proliferation. (2) The selective action displayed by this body for one particular cell, and the direct descendants of that cell, to the exclusion of others of the same type. (3) The apparent impossibility of infecting healthy individuals with the blood of cancer patients, but only by means of intact cells. It may also be said that this line of reasoning is in accord with the findings of those who have investigated tumors with a view to discover some form of parasite.—*Buffalo Medical Journal.*

**Summer Care of Frail Children.**—J. Madison Taylor says that children who continue to manifest a low degree of vitality and slackness in play, always deserve our tenderest care and most diligent investigation. The first safeguard must be to defend them from fussy, parental experimentation and spasmodic over-attention. Quiet is the paramount requisite, and open-air life. The light of the sun is of first importance, but in certain weather this may be too severe. The physician must, of course, ascertain whether there is any impairment of activity in any special organ, and supply appropriate treatment, which can often be best applied mechanically to the spinal area through which these can be reached, for in children, lack of vigor, as a rule, indicates a disturbance of nutrition in the segments of the cord whence arises the vascular innervation to the parts or organs most below par. The author gives careful directions as to the hygienic measures to be observed. Exercise in the form of gardening is especially recommended. Often in frail children motor education is a matter of supreme importance.—*International Medical Magazine.*

**A Modification of Talma's Operation for Ascites.**—Arthur E. Barker performed an operation in the following manner: The abdomen was opened in midline below the navel. When the ascitic fluid had for the most part run off, the omentum, which was very thick and sclerosed, was drawn out and divided down to its middle into two long lobes. The thickened and vascular parietal peritoneum was now stripped off from the abdominal wall on both sides of the medium incision over an area about the size of the hand. In the pockets so formed, a transverse cut was made above in each case for about one and one-half inches. Through the holes thus formed, each lobe of the omentum was passed into the pockets on either side, spread out all over the pocket, and secured to its lowest point by one or two sutures. The abdominal wound was then closed in the usual manner. What was hoped was that the two portions of omentum, being now covered by raw surfaces of vascular connective tissue on both sides, would rapidly become incorporated with the abdominal wall. As it was a question of serous membrane applied to connective tissue and not to serous membrane, the adhesions ought to be firm and permanent, and so lead to an anastomosis of the vessels of both systems, the omental and parietal. Only eight months have elapsed since the operation, but so far there seems good hope of improvement, and the patient is well satisfied with the result.—*Edinburgh Medical Journal.*

### ACUTE BULBAR PARALYSIS DUE TO HEMORRHAGE AND SOFTENING OF THE PONS AND MEDULLA.

WITH REPORTS OF CASES AND AUTOPSIES.

By CHARLES L. DANA. A.M.. M.D.,
NEW YORK.
PROFESSOR OF NERVOUS DISEASES, CORNELL UNIVERSITY MEDICAL COLLEGE; VISITING PHYSICIAN TO BELLEVUE HOSPITAL; NEUROLOGIST TO THE MONTEFIORE HOME.

*Introduction.*—The causes of acute bulbar paralysis in all its forms are extrinsic and intrinsic. The *extrinsic* causes are lesions of the cerebral hemispheres, usually double, but sometimes single. These lead to bulbar symptoms, which are usually associated with other symptoms, such as hemiplegia, and form what is known as pseudobulbar paralysis. Acute ascending multiple neuritis may also lead to bulbar symptoms, and also certain toxic conditions, such as paralytic rabies and acute ascending paralysis. Acute bulbar paralysis is also sometimes caused by a purulent meningitis and by caries of the upper cervical vertebræ or of the occipital bone.

The *intrinsic* causes of acute bulbar paralysis are hemorrhages, softenings from thrombus or embolus, acute poliencephalitis, and suppurative encephalitis. In late years it has been found that a good many cases of acute bulbar disturbances, of more or less limited character, are due to inflammatory processes, and literature of recent years contains rather more upon these inflammatory conditions than upon hemorrhages or softenings.

**Hemorrhage of the Pons-medulla.** It will be my purpose, however, in this paper to discuss simply acute lesions of the pons and the medulla, due to hemorrhages or softenings. Hemorrhages of the pons are comparatively rare. The figures given by those who have collected statistics make the range of frequency vary from less than 1 to nearly 10 per cent. on all hemorrhages. The later and more careful statistics seem to show that pons hemorrhages, as compared with cerebral hemorrhages, are not more than 2 per cent. This about coincides with my own experience. Among sixty consecutive cases of intracranial hemorrhage which I, personally, have seen, only two were pons hemorrhages.*

*COMPARATIVE FREQUENCY OF HEMORRHAGES:

Hemorrhage of the brain, 30 cases.
Hemorrhage of the pons, 6 cases. —ROCHOUX.

Hemorrhage of the brain, 386 cases.
Hemorrhage of the pons, 9 cases. —ANDRAL.

Hemorrhage of the brain, 757 cases.
Hemorrhage of the pons and peduncles, 76 cases.
—GINTRAC.

Hemorrhage of the brain, 153 cases.
Hemorrhage in the protuberance, 21 cases.
—DURAND-FARDEL.

Hemorrhage of the brain, 912 cases.
Hemorrhage of the pons, 91 cases. —FAGGE.

It is interesting to add, in this connection, that Pitt found, among 9,000 post mortems in Guy's Hospital, aneurysms of the basilar artery only nineteen times.

Hemorrhage of the medulla is still more rare than hemorrhage of the pons (only two cases in seventy-five having been reported). I have never seen such a case with autopsy. Of the frequency of thrombotic and embolic softening of the pons and medulla I have no extended statistics. My own experience is, however, that they are more frequent than hemorrhages, and certainly the literature of the subject would show such to be the case. In my own experience the percentage of thrombotic softenings of pons and medulla to cerebral softenings has been about 6 per cent.

*Historical.*—The first communication upon hemorrhage in the pons was made by Cheyne, in his work on Cases of Apoplexy and Lethargy, London, 1812; a little later a case was reported by Burdach (1819), and one by Serres in the same year. These individual reports were soon followed by a long series of cases by the French authors: Rochoux, Cruveilhier, Gintrac, Andral, Longet, Ollivier, Durand-Fardel; by the English: Bright, Abercrombie, and Parker; and by the Germans, Mohr, Romberg, and Bamberger. In 1851 Josias collected a series of fourteen cases. In 1856 Gubler called attention to the diagnostic importance of the so-called "alternate hemiplegia" which has been recognized as characteristic of lesions of the pons. The next most important work upon this subject was by Larcher (Pathologie de la protubérance annulaire, Paris, 1868). In 1877 Bode, in an inaugural thesis, published at Würzburg, collected the histories of sixty-seven cases and wrote a monograph of much value upon this subject, contributing also several cases of his own. In 1899 Dr. Hans Luce, in *Deutsche Zeitschrift für Nervenheilkunde*, Vol. XV, p. 327, collected a series of eighteen cases of pons hemorrhage, and studied them with reference to the question of the convulsions produced by pons lesions.

Since the time of Bode's monograph, I can find no extensive or complete contribution to the subject of hemorrhages in the pons and medulla, though there have been a considerable number of special reports and studies.

I have not attempted to present a full bibliography of hemorrhagic apoplexy of the pons or of the acute softening of the pons, but have utilized the statistics of Bode, Larcher, and Luce, and have collected the important cases from that time, 1877, until the present.

*Points of Investigation.*—A study of the statistics, of the histories of the cases, and of the discussions brought out by them, show that there are a number of points of practical interest which deserve attention at the present time. One of these is the alleged resemblance of pons apoplexies to opium poisoning, a resemblance which has led to a good many mistakes, and is a point which is sometimes of medicolegal importance; another question is that of the relation of convulsions to diseases or lesions in the pons and medulla; a third, the question of the frequency and etiology of lesions of these parts; a fourth, the symptomatology of these lesions, particularly the study of

certain special symptoms and syndromes, and the characteristic dissociation of sensibility; a fifth, the anatomical studies which have been brought out by the investigation of the secondary degenerations from these lesions, and by the disturbance of function caused by certain specially localized lesions.

*Anatomical and Physiological.*—The mid-brain, which includes the cerebral peduncles and corpora quadrigemina; the hind-brain, including the pons, cerebellum and its peduncles; and the after-brain, or medulla, form a unit which is called the brain-stem. This brain-stem is supplied with blood mainly from the vertebral arteries, which themselves rise from the subclavian arteries and run a long, tortuous course within the transverse processes of the cervical vertebræ. Before uniting to form the basilar artery, they give off branches to form the anterior spinal artery and the inferior cerebellar artery, which latter gives off the posterior spinal arteries. (Fig. 1.) The basilar, which is formed just before the vertebrals reach the ventral surface of the pons, gives off the transverse arteries, the median cerebellar arteries, the superior cerebellar and the posterior cerebral arteries, all of which may be considered transverse arteries of varying size. All of these vessels give off branches to the cranial nerve nuclei, and nerve roots, and various accessory branches to the gray and white matter. The left vertebral artery is a little larger than the right, and each vertebral artery is a little smaller than the basilar.

The vascular supply of the mid and hind-brain is fairly well differentiated: the vertebral arteries and their branches supply the medulla, with its contained cranial nuclei, namely, those of the eighth, ninth, tenth, eleventh, and twelfth nerves. The basilar artery and its branches supply the pons and its contained cranial nuclei, third, fourth, fifth, sixth, seventh and eighth nerves. The cerebellum is supplied partly by the branches from the vertebral and partly by branches from the basilar (middle and upper cerebellar). (Fig. 1.)

The nuclei of origin of the third and fourth nerves are supplied specifically by median arteries given off from the upper part of the basilar. The roots of the third and fourth are supplied by root arteries from the same source. The peduncles are supplied by accessory branches from the posterior cerebral. The tubercular quadrigemina are supplied by branches from the posterior cerebral anteriorly, and the inferior cerebellar posteriorly. (Duret.)

The posterior cerebral artery, though given usually by the basilar, is essentially a cerebral artery, and supplies the occipital portion of the brain.*

The pons and medulla contain, speaking generally, long tracts of nerve fibers which run between the cerebrum and cerebellum and the spinal cord; transverse tracts which connect the lobes of the cerebellum; various short association tracts, and finally, nuclear deposits for the cranial nerves and the various long and short tracts.

The course of the long voluntary motor tracts from the brain to the nuclei of the motor-cranial nerves and to the spinal cord is well known and need not be rehearsed here.

Besides these long voluntary tracts there are long efferent tracts from the frontal and temporal lobes which end in nuclei in the ventral pons, and these send fibers to the cerebellum. These frontopontine and temporopontine tracts have probably to do with the automatic coördinated muscular movements of the body and extremities.

They are also pontothalamic fibers which have to do perhaps with involuntary movements of the face and body in expression, and hence there may be in pseudo-lesions forced laughing and crying.

The long afferent or sensory tracts from the spinal cord to the cerebellum and cerebrum consist of the nerves for cutaneous sensation of touch, temperature and pain, the nerves of muscle and articular sense (deep sensibility), the nerves of coördination and equilibrium.

1. The fibers of the *sense of touch* do not seem to have a definite path. Some cross and some do not in the cord. Some appear to go up in the posterior columns with the muscular sensory tract, while some pass up in the lateral columns. Their exact course in the medulla and pons is not known; they cross in part, seem to go part with the muscular tract and not with that of pain and temperature; they probably pass diffusely through the formatio reticularis.

2. The fibers carrying ***sense of temperature and pain*** cross in part, at least, in the spinal cord; they ascend in the deep parts of the posterior horn and in the lateral columns (forming part of

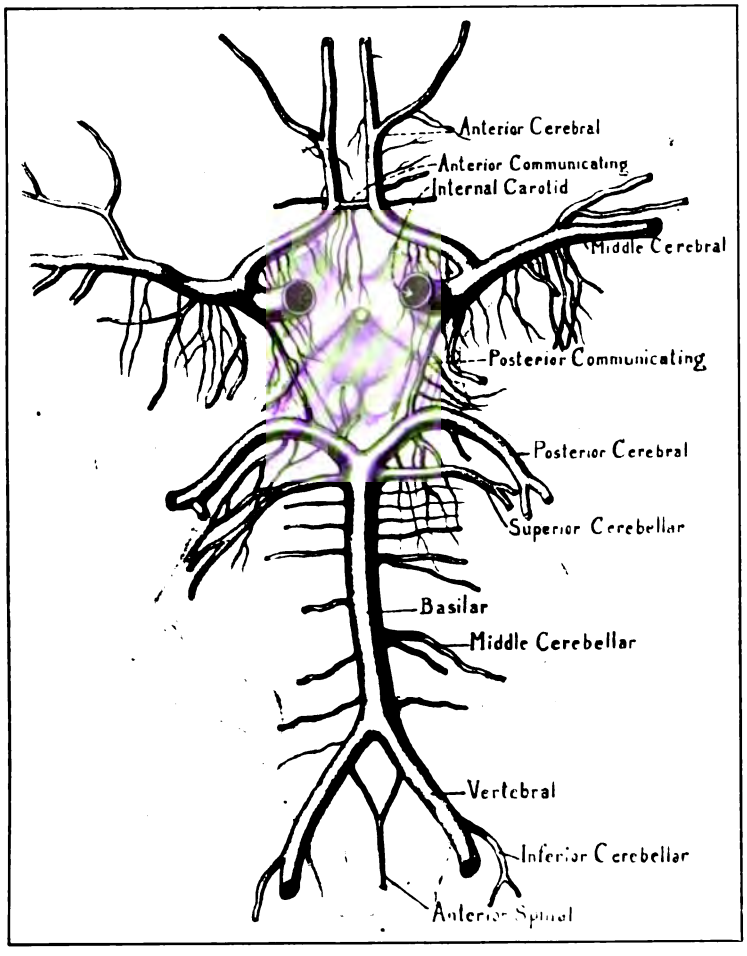

FIG. 1.—Circle of Willis and arteries at the base of the brain, drawn from specimen prepared for author by Dr. McLean. It shows the relative proportion of the different arteries and the actual number of small and large branches. (Drawn by Shannon.)

*According to D'Astros, the posterior cerebral artery gives off five sets of small branches: (1) to the internal parts of the peduncles, called the internal peduncular; (2) external branches to the external part of the peduncles; (3) arteries of the fissure; (4) arteries of the superior peduncles; (5) arteries of the corpora quadrigemina.

ventro-lateral tract of Gowers). As they enter the medulla, they lie to the outer side of the olivary bodies and pass up in the lateral and dorsal part of the medulla, separated quite a little from the muscular-sensory tract. As they reach the pons, however, these two sensory pathways get rather closer together. At the upper part of the pons many (and most of the fibers of the Gowers' tract proper) curve back through the anterior peduncles of the cerebellum, into that organ. Other fibers, however, go through the tegumentum to a nucleus of the thalamus and thence to the sensory-motor convolutions of the cortex.

the lemniscus or fillet. This fillet gradually passes away from the middle line toward the side of the pons, and finally gets near its periphery ascending into the tegumentum and between the corpora quadrigemina above and the motor tracts below, the fibers continue up ending in the thalamus and cortex. From the beginning some fibers (arcuate) are sent also to the cerebellum, mostly crossing.

4. The paths for the *sense of equilibrium* pass up in the direct cerebellar tract and run uncrossed in the corpus restiforme to the cerebellum. Similar fibers representing the equilibrium nerve run from the inferior olive to the cerebellum also in the

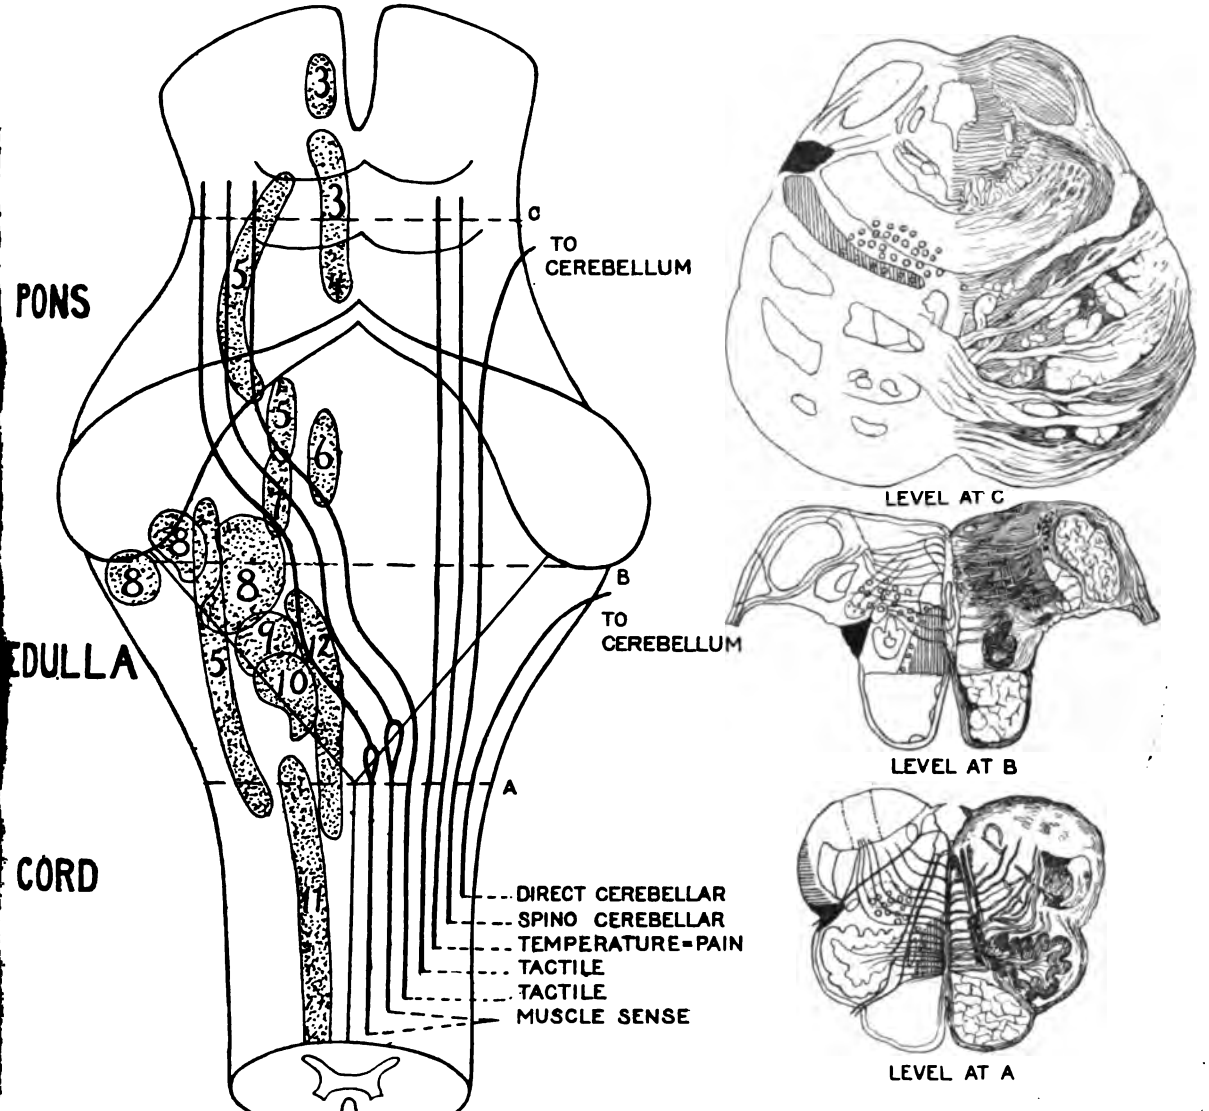

FIG. 2.—The figure on the left shows, on the left half, the location of the nuclei of the cranial nerves. On the right half the courses of the different long afferent tracts are shown. The figures on the right show transections of the pons and medulla at levels A, B, and C. The location of the different afferent paths is indicated as follows:
1. Area shaded with vertical lines—muscle sense path.
2. Area shaded with horizontal lines—direct cerebellar tract.
3. Area of small circles—tactile sense.
4. Area of solid black—temperature-pain sense (part of Gower's tract).
The oval areas, indicating the position of the nuclei of Goll's and Burdach's columns, should be longer.

3. The fibers carrying *muscular sensation* ascend the spinal cord uncrossed until they reach the nuclei of the columns of Goll and of Burdach, at the upper end of the cervical cord. The former nucleus receives the fibers from the lower extremity, the latter those of the upper extremity. The fibers then cross in the medulla forming the sensory decussation. The fibers from the lower extremity pass lower down, *i.e.* more caudally, than those from the upper extremity. They then pass along forming the interolivary tract (ribbon of Reil) near the raphe or middle of the medulla and between the inferior olives. They tend, as they reach the pons, to spread out laterally, forming a flat band called corpus restiforme, the fibers of equilibrium from the vestibular branch of the eighth nerve run also in the corpus restiforme.

The position of the foregoing tracts and of the cranial nerve nuclei is shown in Fig. 2.

There is in the medulla a center for the cervical sympathetic fibers; it is perhaps (Onuf, Collins) in a group of cells lying near the solitary bundle. It is, at any rate, near the origin of the vagus and glossopharyngeal. And, as a consequence, in lesions of the medulla, we may get flushing and sweating of the same side of the face, retraction of the eyeball and narrowing of the palpebral fissure, and contraction of the pupil.

The pulse and respiration are disturbed through injury or irritation of the vagus, but much less in softening than in hemorrhage.

The temperature seems mainly to be affected in irritation and destructive lesions causing compression, such as hemorrhages, and mainly in hemorrhages of the pons.

*Etiology of Hemorrhage, Sex.*—Among 46 cases with autopsy collected by myself, there were, males, 26; females, 20. The statistics of Bode give, males, 40; females, 25; of Larcher, males, 29; females, 15. Total, males, 95; females, 60. The proportion of males to females is therefore not quite 2 to 1.

*Age.*—The statistics collected by myself and others give the following:

| | DANA. | BODE. | LARCHER. | TOTAL. |
|---|---|---|---|---|
| —20 | 2 | — | — = | 2 |
| 21—30 | 6 | 8 | 14 = | 28 |
| 31—40 | 7 | 10 | 17 = | 34 |
| 41—50 | 15 | 12 | 24 = | 51 |
| 51—60 | 8 | 9 | 3 = | 20 |
| 61—70 | 6 | 10 | 15 = | 31 |
| 71— | 2 | 10 | 12 = | 24 |
| | | | | 190 |

This shows that one-fourth of the cases occur in the fourth decade of life; next oftenest between thirty and forty, and between sixty and seventy. The cases under twenty occurred, one at birth in a difficult labor (Dr. Schultz) and one at eighteen, in status epilepticus. The age range differs from that of cerebral hemorrhage, in that practically no cases occur in childhood.

*Other Causes.*—The most frequent of the determining causes mentioned are nephritis, with cardiac hypertrophy and arterial sclerosis. These factors were mentioned fourteen times in forty-four cases. Alcoholism is a concomitant cause, but not very often noted. Syphilis is also rarely observed. Among other causes mentioned are, status epilepticus, forceps delivery, caisson pressure, pernicious anæmia, gastroenteritis, caries of cervical vertebra, meningitis, and secondary hemorrhage from tumors.

The etiological factors seem to be much more often those associated with cardiac hypertrophy, arterial sclerosis and renal disease and are in the same line as the causes of cerebral hemorrhages. Syphilis seems, however, to be decidedly less often a factor. At any rate, I can find it referred to only three times in forty-six cases. Severe exertion has not been found to be an exciting cause, though it is a disease associated with the laboring classes more than is cerebral hemorrhage. Almost all the statistics are from hospital records. Thus, it may be said in general that those who work more with the fore-brain are more liable to hemorrhages there.

*Pathological Anatomy.*—The medulla is sometimes somewhat involved in the pontine hemorrhages, but I can find only two cases of hemorrhage in this part. (Lemcke, Jackson.)

Hemorrhages in the pons are apparently, usually, very severe, but this is due in part to the fact that we base our statistics on cases with autopsy. Probably there are other milder cases which cannot be differentiated from softenings.

| | BODE | DANA. |
|---|---|---|
| Large part of pons destroyed | 27 | 12 |
| Focus in or near center | 17 | 10 |
| More on right side | 18 | 15 |
| More on left side | 13 | 12 |
| Multiple foci | | 5 |
| Cerebral hemorrhage | | 3 |
| Pons and medulla | | 2 |
| Large and breaking into fourth ventricle | | 8 |

Peduncular hemorrhages which may involve some of the pons are not included in these statistics.

Thus, while the earlier statistics of Bode show a large number of severe and total hemorrhages, the later reports show, relatively, more involving only one side. Still there is no doubt that pons hemorrhages have a tendency to invade the median parts, and make a large focus of destruction. Fagge states that out of twelve pons hemorrhages, five broke into the fourth ventricle.

The arteries oftenest involved are the transverse and median branches of the basilar. The basilar itself is rarely ruptured, nor do we find rupture of the vertebrals, or of the posterior cerebrals. There is often found aneurysmal dilations of these arteries, and the pathological process is similar to that in cerebral hemorrhage. There is sometimes a basilar aneurysm, and it is probable that by atheroma and thickening the passage of blood into the posterior cerebrals is made less free, and the blood, consequently dammed back and thrown into the small arteries of the pons. Atheromatous patches on this artery are often observed, and the transverse arteries develop small aneurysms as in cerebal cases. In only two of my collected cases was there any associated focus of cerebral hemorrhage or softening found, in which respect pons hemorrhage differs from pons softening. Capillary hemorrhages were found in three of my collected cases—one of pernicious anæmia, one the case of status epilepticus, and one in a woman of sixty-one. (Cohn.) Durand-Fardel reports a case in an old woman, and several others have been reported. Such cases belong more properly to acute softenings. Multiple foci of hemorrhages occur rarely. More than two were reported in five cases. (Raymond, R. Ronnell, Urain).

*Symptoms.*—The only type of pons hemorrhage which can be really described as having a characteristic *syndrome* is that in which the hemorrhage is severe, either involving a large part of the pons, or breaking into the fourth ventricle or both. The smaller hemorrhage causes symptoms which partake, in a measure, of the typical cases, but shade off into types resembling the acute softenings.

It has to be remembered that about one-half of all pons hemorrhages are severe and typical, that the medulla is usually spared, or is, at least, not primarily involved, and that the posterior cerebrals which supply the peduncles and the occipital lobes are rarely involved in hemorrhages. The pons itself, then, is the part most injured. Besides the motor, sensory and transverse cerebellar tracts, it contains in its dorsal part the nuclei and fibers of origin of the V, VI, VII, and VIII cranial nerves. In almost any severe lesion we would expect involvement of the V (trigeminal), and VI (abducens) nerves; if high up, involvement also of the III (motor oculi); if low down, involvement of the VII (facial), VIII (acoustic).

Only when the medulla is involved would we expect serious involvement of IX (glossopharyngeal), X (vagus), XI (spinal accessory), and XII (hypoglossal).

It is not my purpose to go minutely into the analysis of the symptoms here. The general history of an attack is somewhat as follows: The patient has some prodromal headaches and malaise for a few days, with vertigo and sometimes vomiting. Then he falls suddenly, as if by a lightning stroke, into a coma, usually very profound. There are twitchings of the face or of the limbs or both, but rarely any general convulsion (three cases). The face is flushed, there is a fall of temperature and the pulse is irregular, but not markedly increased or slowed; as a rule, the respiration is slow, 4 or 6 per minute, or more often irregular, and of Cheyne-Stokes type. The pupils are contracted to a pin-point, and do not respond to light, but may be

uneven. There is convergent strabismus or conjugate deviation of the eyes. The limbs are at first stiff, but may be relaxed later and the reflexes increased.

The patient cannot be aroused, but can be made to vomit. A few hours later the temperature rises, sometimes very high—106 to 108—but usually not. There are involuntary movements of the bowels, swallowing is impossible; evidences of dyspnœa are shown. The pulse becomes more rapid, cyanosis develops, the patient dies in six to twenty hours, usually with evidence of paralysis of respiration.

If the hemorrhage is less severe, the coma is less profound or may be absent, the patient shows signs of agonizing suffering and difficulty in respiration, evidences of crossed paralysis, crossed anæsthesia and disturbance of equilibrium and ataxia can be noted.

In still smaller lesions we find no such severe general symptoms, but only those due to a circumscribed focus in one side of the pons, because the smaller lesions are unilateral. The syndrome of pons lesions then is:

1. Headache, malaise, vomiting.
2. Sudden and profound coma.
3. Twitching of the face and limbs or both.
4. Myosis and convergent strabismus or conjugate deviation (away from the side of the lesion).
5. Slow, irregular breathing.
6. Irregular pulse.
7. Dysphagia.
8. Paralysis of limbs or crossed paralysis and exaggerated reflexes.
9. Gradual rise of temperature, sometimes to high point.
10. Death inside of twenty-four hours.

The *prognosis* in severe pons hemorrhage is very bad, death occurring, as already stated, in a few hours. What proportion of all cases get well I cannot say, but as most of the cases of acute bulbo-pontine apoplexies which recover give a history pointing to softening, it is probable that a great majority of hemorrhages are fatal.

### REPORTS OF CASES.

CASE I.—*Hemorrhage of the Pons.* Pauline K., aged twenty-four years, German, admitted to Bellevue Hospital February 17, 1898. Family history negative. Denies all syphilitic history. About three weeks previous, while menstruating, some water was thrown over her and the menses were stopped. She then began to have fainting spells, from which she would soon recover. After having had several of these attacks her speech became affected. Then she began to have trouble in using her left arm and later her left leg, until she became completely paralyzed on the left side. When the patient was admitted to the hospital she seemed well nourished, with flushed face, tongue dry and coated and breath offensive. She was restless and apathetic and in a semi-stuporous condition. The pulse was regular, about 116, respiration 24, temperature 99½°. The lungs were normal, and the heart had a faint systolic murmur at the base. The left arm was paralyzed and the left leg rigid; the right side of the face was paralyzed. There was some difficulty in swallowing and some indistinctness in speech. The epigastric reflexes were absent. Wrist- and elbow-jerks increased more on the right side; knee-jerk increased, slight ankle clonus, but the reflexes were difficult to determine in the left leg owing to its rigidity. The conjunctiva of the right eye was congested. The face was flushed and there was marked dermographia. There were onstipation and retention of urine.

On the 18th paralysis of the right facial was present and the eye could not be closed. There was some paralysis of the right external rectus; the pupils were small and responded to light, but the reaction was slow. The temperature on this day had fallen to 98°, the pulse was 106, and respiration 28. The urine was 1025, acid, no albumin, no peptones; urea .014. The temperature had gradually increased on the 18th, until at noon it was 100⅘°, and on the morning of the 19th gradually rose to 105⅘°, the pulse rising to 140 and the respirations to 32 and finally to 44. The patient grew more stuporous and had four slightly convulsive attacks during which she frothed at the mouth. These attacks were not, however, epileptic, but rather accesses of rigidity, with staring of the eyes. She died on the morning of the 19th, two days after admission. No evidences of anæsthesia could be obtained, and the symptoms consisted, therefore, of a paralysis of the sixth and seventh nerves on the right side, and paralysis and rigidity on the left, with dysarthria and dysphagia, slight convulsive attacks and further high terminal temperature.

An autopsy was made by Dr. Harlow Brooks, and it was noted on the autopsy that the left pupil was smaller than the right. I omit items not connected with the nervous system, or of special importance with relation to this case.

The heart was practically normal; the arch of the aorta showed slight endarteritis, and the coronary artery very slight endarteritis. The caliber of the carotid arteries appeared somewhat diminished in size. The abdominal and thoracic viscera practically normal, and showed no signs of syphilis.

The blood vessels at the base of the brain were intensely congested and in places contained thrombi.

The pia mater was thickened and opalescent over the frontal convolutions; the basal ganglia congested, but there was no lesion in the cerebral hemispheres.

Just to the right of the median line in the anterior portion of the pons is found a hemorrhagic area, 1 to 2 cm. in diameter, extending back through the pons until it occupied almost the entire right side of pons and extends in area to left side, extending backward becoming narrower, till it finally terminated in the posterior surface of pons, left side. The vessel of left side—the tissue of medulla and cervical segments of cord and cerebellum—were apparently normal. The center of involved area contained a clotted mass evidently surrounding a small blood vessel and a small artery leading into involved area at the anterior portion of pons was found, the lumen of which is plugged. Pituitary gland, usual size.

CASE II.—*Hemorrhage of the Pons.* The patient, a man, aged about fifty years, was brought to the hospital suffering from vertigo headache. While walking along the ward on his entrance to the hospital he suddenly fell down in deep unconsciousness and almost immediately expired. No history could be obtained of him. On autopsy a large hemorrhage was found in the pons near the raphe. No notes were taken at the time and the case has little except statistical interest.

**Acute Softening of the Pons-medulla.**—*History.*—After Duchenne had in 1860 described the malady known since then as progressive "glosso-labio-laryngeal palsy," attention was drawn to bulbar palsies of other types and due to other causes. Griesinger (1862) and Lebert (1866) collected and reported cases showing that bulbar palsies might be due to local aneurysms and to softening from other vascular diseases. Joffroy in 1872 emphasized the distinction between degenerative or protopathic

palsy and palsies from other causes; further contributions were made by Hallopeau (These de Paris, 1875), Lichtheim (*Deutsche Archiv für klinische Medicin*, Band XVIII) and Nothnagel (Diagnosis, 1879). In 1885 Oppenheim and Siemerling (Charité-Annalen, Vol. XII) described the different forms of acute bulbar palsy and pseudobulbar palsy, and they gave a bibliography and short analysis of the important cases of acute softening reported up to that date. The cases which I have studied include some not mentioned by these last authors and most of those reported since their article, including my own.

Nearly all the cases utilized in drawing conclusions were reported with autopsy; but there have been some very careful studies made on clinical cases which have much value, for it is comparatively easy to make the local diagnosis, at least in pons-medulla lesions.*

*Etiology.*—Among thirty-nine collected cases, with autopsies, four being personal observations, I found males, 27; females, 11, showing a ratio of over two to one in favor of the male sex. In acute softening, the proportion of males is greater than it is in hemorrhage.

The age relations are shown in the following table:

| | | |
|---|---|---|
| —30 | = | 0 |
| 31—40 | = | 9 |
| 41—50 | = | 10 |
| 51—60 | = | 7 |
| 61—70 | = | 3 |
| 71— | = | 4 |
| | | 33 |

There are no records of acute softening before the age of thirty. The favorite age is between thirty and fifty, during which period most of the softenings are luetic. In old age they are due more to senility and degenerative changes in the arteries.

Among the other causes lues was found in 11, arterial sclerosis in 9, nephritis and arterial sclerosis in 14, cardiac disease in 14, alcoholism in 1, senile atheroma in 2.

No doubt, lues plays a greater part than is shown here, while the arterial changes associated with alcoholism, nephritis, and cardiac hypertrophy are less prominent than in hemorrhage. In two cases the patients were insane and in three other cases the patients were in the early stage of general paresis. In two cases the patients had locomotor ataxia; local tumors, and aneurysm of the vertebral arteries were found in two cases. Schlesinger (*Zeitschrift für klinische Medicin*, No. 32, 1896) mentions three cases caused by sudden lowering of atmospheric pressure on coming out of a caisson.

No special exciting causes could be made out.

It appears to me that excessive work and worry in anæmic and poorly nourished women leads sometimes to bulbar apoplexies.

The great cause of acute bulbar softenings in early and middle life is syphilis. The attacks are not rarely premonitory of an impending tabes or paresis; they indicate that the disease has a rather serious hold on the nervous system, and are of more importance than the casual cranial nerve palsies due to meningitic exudates.

In old age softenings occur because there has been a particularly serious degree of atheroma and sclerosis of the bulbar vessels. What determines it we do not know, but as I said of hemorrhage, it seems that hard manual labor combined, perhaps, with anxiety seems to lead to pathological changes in the vessels of the brain.

*A very complete bibliography of bulbar diseases of all kinds is given by Van Oordt, *Deutsche Zeitschrift für Nervenheilkunde*, Vol 8, p. 137, 1896.

*Symptoms.*—The prodromal symptoms of acute bulbar softening are generally those of an endarteritis and of a syphilitic invasion of the brain. In a small proportion of cases (about 20 per cent. in my statistics) there has been, some months or years previously, thrombosis of a cerebral artery, and consequently, cerebral hemiplegia. The prodromal symptoms then are occasional preliminary attacks of hemiplegia, vertigo, numbness in the limbs, headache, temporary speech disturbance and double vision. Just before the attack in particular the patient may suffer from vertigo, noises in the ears, hoarseness, vomiting, and headache. The Stokes-Adams syndrome may be present (Brissaud). The attack may also be preceded by symptoms of nervous agitation and even of slight mental disturbance, especially in the luetic cases.

The seizure itself is usually sudden, and within a half hour, or an hour, is very nearly complete, usually being accompanied with headache, vertigo and perhaps vomiting. In other cases the symptoms may come on in two or three successive slight attacks, continuing over several days.

After the attack the patient is affected with symptoms depending upon the situation of the lesion. In practically all cases, however, there are two sets of phenomena: first, the bulbar symptoms and second, some form of sensory or motor hemiplegia. The bulbar symptoms consist of ocular motor palsies, a facial or trigeminal paralysis, or both, disturbances in the equilibrium, vertigo, rotating in the ears, difficulty in speech and deglutition. There is rarely any change in temperature. The pulse may be slow or irregular. The hemiplegic symptoms consist of a paralysis, usually, but not always, on the side opposite the cranial nerve involved, so that there is an alternating or crossed hemiplegia, associated with some form of anæsthesia.

The symptom groups in pons-medullary lesions may be of three types:

1. The syndrome of medullary softening. The lesion is of the inferior cerebellar or vertebral or some of their branches.

2. The syndrome of pons softening. The lesion is of some of the transverse branches of the basilar.

3. A general syndrome, including symptoms seen in lesions of both pons and medulla, or in lesions in which the focus, while lying mainly in one part extends into the other. The lesion is a thrombosis or embolism of the vertebral just as it joins the basilar, and leading to some occlusion of the basilar.

1. *The Syndrome of Medulla-softening.*—When the medulla chiefly is affected with focal softening it is due usually to a thrombosis of one of the vertebrals. It may, however, be due to lesion of the inferior cerebellar artery, or of a small branch of this artery or the vetebral. The symptoms vary with the extent and locality of the lesion, but there is a general group which is certainly more common than any other, and which may be said to characterize softenings in this area. These symptoms are:

Disturbances of speech and of swallowing.

Hemiplegia.

Disassociation of cutaneous sensations, there being an anæsthesia to pain and temperature but not of touch upon the affected side.

Ataxia involving either the arm or leg, or both, of the side opposite the paralysis. This ataxia is due to loss of deep sensibility, and there is defective sense of position and astereognosis.

With the ataxia, or perhaps, without it, there may be what Babinski terms *asynergy*, that is to say, a loss of the coördinating activity of the volitional

impulses, so that one segment of the limb is moved without harmonious action with the other. This condition would ordinarily be classed as a form of ataxia.

There is a condition of forced movements, or tendency to fall to one side (lateropulsion).

There is often, though not always, an evidence of paralysis of the sympathetic upon the side of the lesion, shown by a contraction of the pupil upon that side, a diminution in the size of the palpebral fissure, with retraction of the globe, and some congestion of that side of the face.

Besides these rather typical symptoms, we often get some paralysis of the tongue, from involvement of the twelfth nerve, and some disturbance of the heart action. There may be, also, involvement of the trigeminus through injury of the descending root, vertigo and noises in the ears, possibly deafness, and there may be even a facial palsy upon the side opposite the hemiplegia, though this is more common in pons lesions. Some disturbance, also, may occur in the oculomotor nerves, especially the sixth, through involvement of the nucleus of that nerve and of the posterior longitudinal bundle. Convulsions and spasmodic movements are not observed, nor forced laughter and weeping. The lesion is sometimes so extensive as to involve somewhat both sides of the medulla, and then there may be motor and sensory disturbances upon both sides of the body. The importance of the foregoing group of symptoms has been especially emphasized by Babinski (*loc. cit.*).

2. *The Syndrome of Pons Softening.*—Lesions in the pons are most apt to be in the ventral part, near the raphe, and next to this, in the dorsal part of the pons, from involvement of a branch of the basilar artery.

Lesions in the pons have no such single characteristic syndrome as those in the medulla. There are some very clear-cut cases in which there is paralysis of the fifth or of the seventh nerve upon one side and hemiplegia upon the other (crossed hemiplegia), but this type of case is not by any means the most frequent. Lesions in the pons may occur without any involvement of the cranial nerve nuclei, except those connected with deglutition and, perhaps, of speech. (Case 1.) When they occur in the ventral region, there are necessarily disturbances of motility, shown by hemiplegia, by irritative motor disturbances, such as twitchings, and sometimes by forced laughter or weeping and morbid emotional states.

When the lesions are deeper in, reaching nearly to the floor of the fourth ventricle and the gray matter, we begin to get involvement of the sensory tracts, and to have hemianæsthesias. These hemianæsthesias are usually also those of pain and temperature only, and thus, *disassociation of sensibility* is characteristic also of pons lesions.

When the nerve nuclei are involved, it is almost always the nuclei of the motor nerves of the eye and of the trigeminus. So that we may get oculomotor palsies with some trigeminal disturbance upon one side, and hemiplegia, with or without anæsthesias, upon the other.

There are in pons lesions also vertigo, disturbances of hearing and some cerebellar symptoms, but not so often the forced movements that we see when the posterior cerebellar peduncle is involved in strictly medulla lesions. In pons lesions high up the fifth and seventh nerves may be involved on the same side as the hemiplegia. In pons lesions, *dysarthria is more often absent* than present. Thus, Markowski collected eighteen cases of one-sided lesion and found dysarthria absent in ten. In general, then, the absence of involvement of the cranial nerves, from the eighth to the twelfth, the absence of marked sensory troubles, except of the fifth nerve, the *presence of forced laughter* and weeping, motor irritability and the involvement of the oculomotor nerves and of the fifth nerve, would suggest a pons lesion.

The abdominal and skin reflexes are often feeble. Sometimes there is a great deal of pain from irritation of the fifth nerve, and sometimes the pupil may be dilated.

It is possible to have a pons lesion simulating almost exactly a cerebral hemiplegia (Case III), but this is extremely rare. If there is evidence of a bulbar lesion and there is not a crossed paralysis, the lesion must be high in the pons.

3. *The Syndrome of Pons-medullary Softening or Acute Softening of Both Pons and Medulla.*—The symptoms here are really only an extension of the type of medullary softening, the lesion being, as stated, usually a thrombosis which involves the vertebral at its junction with the basilar. The syndrome is a fairly definite one, but mainly so in that it is an enlargement of the picture seen in pure medullary lesions.

Thus we have:

(1) Hemiplegia; (2) pain-temperature, (3) anæsthesia on the same side as hemiplegia; (3) loss of deep (muscular) sensibility, with ataxia, often on opposite side to hemiplegia; (4) lateropulsion to side of lesion; (5) paralysis of various cranial nerves, especially seventh to twelfth, on the side opposite hemiplegia, (6) dysphagia and dysarthria; (7) paralysis of sympathetic on same side as lesion, with myosis and retraction of globe; (8) subjective sensations of vertigo, roaring in ears, pararthria and pain; (9) disturbances in rhythm of pulse and respiration.

*Study of Special Symptoms of Acute Pons-medulla Softenings.*

*Hemiplegia* occured in a little more than one-half of the observed cases, and may be more accentuated in the arm or leg, usually in the arm. Occasionally, with hemiplegia upon one side, there is some weakness of the side opposite, that is, on the same side as the lesion. Hemiplegia with an ocular palsy is oftenest seen; hemiplegia with crossed facial palsy is relatively rare, while hemiplegia with involvement of the fifth nerve is more frequent. Thus in relative frequency we find hemiplegia and eye palsies, hemiplegia and fifth nerve palsies, and hemiplegia and seventh nerve palsies. Hemiplegia is almost always accompanied with anæsthesia, and this anæsthesia is on the same side as the paralysis. In sixteen cases with hemiplegia, there was anæsthesia on the same side in eleven, on the side opposite in one. The hemiplegia and anæsthesia are often accompanied with disturbances of muscular sense and ataxia, and this disturbance is somewhat oftener on the opposite side from the paralysis, *i.e.* on the side of the lesion. In five cases of hemiplegia with ataxia, the ataxia was upon the same side as the hemiplegia in two and on the opposite side in three. The type case is hemiplegia with pain-temperature anæsthesia on one side and some ataxia on the other.

*Convulsive Movements.*—The view originally exploited by Nothnagel, that there was a convulsive center in the pons, is not confirmed by clinical and pathological experience in man. In lesions of the pons, there are practically never any convulsions, due, at least, directly to this lesion. When the onset is quite acute, and the softening involves the ventral part of the pons and the fibers of the motor tract, there may be some trembling and

twitching, as in the case reported in this paper (case 1).

As regards the convulsions in hemorrhages of the pons, an exhaustive study was made by Luce, who was able to collect, however, only one case in which convulsions occurred. But in spite of this, he is led to conclude that the nuclei in the ventral part of the pons are epileptoginous. There is no doubt that in the acute injuries of the pons, when the ventral part is involved, twitching and tonic spasms occur, involving the face and extremities, with sometimes tremors, but these do not amount to actual convulsions, and it must be borne in mind that in the cases in which convulsions have been observed, the patients had not perfectly normal brains; that is to say, they were suffering from arterial sclerosis, nephritis and possibly uræmia, or paresis.

*Forced laughter and crying* has been noted in three cases besides my own (Bechtereff, Ransahoff, Mills).

It is well established (Kirchhoff, *Archiv für Psychologie*, Bd. XXIV, Heft 3) that there is in the thalamus a center which controls the emotive expression of the opposite half of the face, so that when this is destroyed, though the patient can move the face voluntarily, it remains immobile in laughing or crying. It may be supposed then that when this center is cut off from its control by the cortex, there may be involuntary laughter or crying. This center must be in connection with lower bulbar centers for the motor nerves of expression (VII, XI, XII, third cervical, etc.). And it must to an extent inhibit and control the bulbar mechanism. The movements, however, in crying and laughing are originally purely under bulbar control. (I have reported the case of a baby which lived five days and cried continuously; it had only a spinal cord, medulla, pons, and cerebellum, with the merest rudiment of a thalamus.) Hence it can be understood that when certain pathways from cortex or thalamus to the bulb are cut off or irritated the bulbar centers for producing movements of laughing and crying may be loosened from control and go off in explosions; just as there are exaggerated reflexes, trepidations of the limbs, etc., when the voluntary motor path to the limbs is destroyed; and explosive laughter is like an exaggerated reflex, a trepidation, or an ankle clonus.

*Oculomotor Symptoms.*—Some involvement of the motor nerves of the eyes occurs in about one-fourth of the cases. In pons-medullary lesions it is the sixth nerve and its associated branch from the third to the internal rectus that are oftenest affected. When a serious degree of ophthalmoplegia occurs it means a higher and peduncular lesion. In ordinary pons medullary lesions then we find as the common symptoms: Conjugate deviation, paralysis of conjugate deviation, internal strabismus, convergent strabismus, nystagmus.

The old formula that in cerebral lesions the eyes turn away from the paralysis and toward the lesion while in pons disease it is the reverse, has a very limited application. In cerebral lesions when there is great pressure or very large destructive lesion, the conjugate involvement of the eyes is toward the lesion and away from the side paralyzed, but more often in cerebral lesions there is only enough disturbance to irritate the central tracts to the abducens of the opposite side and the internal rectus of the same side, and the eyes consequently turn away from the lesion.

In pons lesions when there is conjugate deviation away from the lesion it is due to irritation of the central path. More often one sees simply paralysis of conjugate deviation toward the side of the lesion. This is due to a paralyzing lesion of the central path to the abducens. Sometimes there is a convergent strabismus, due to lesion of both abducens. If the sixth nerve root is affected we have simply an external strabismus. Nystagmus is often seen in pons and rarely in cerebral lesions. This is due to various causes, but perhaps chiefly to lesions of the central tegmental tract, or of the posterior longitudinal bundle, two tracts which are concerned in the coördination of the eye muscles and in bringing them into relation with the other cranial nerves.

The contraction of the pupils which occurs in pons hemorrhages must be ascribed mainly to the compression and irritation of the third nerve nuclei and, perhaps, to a coincident palsy of the sympathetic center.

*Sensory Symptoms, Pain, and Paræsthesia.*—Pain referred to the parts supplied by the sensory tract are rarely present. Patients complain sometimes of headache, and occasionally of some burning pain or cold pains, but pure neuralgic pains, except those due to an occasional irritation of the fifth nerve, are very infrequent.

Paræsthesias, on the other hand, are quite common. The sense of numbness and pricking is usually present in the anæsthetic limb or side. Cold pains and burning sensations also occur, and are referred to the anæsthetic parts. The discomfort from these is sometimes very great. In hemorrhages of the pons, when the roots of the trigeminus have been torn up, there is at times great agony from this cause, but I find that central pains from lesions of the pons and medulla, other than those due to irritation of the trigeminus, are very rare. It seems to be a general physiological law that only irritation of the peripheral sensory neuron causes pain. The central pains which are sometimes described as occurring in brain disease, are extremely rare, and it is a question whether they are not, after all, psychical. Even paræsthesias are much less common from lesions of a central sensory neuron than from lesion of the peripheral nerve.

The anæsthesias which occur in the pons and medullary softenings are peculiarly distinctive. The anasthesia is characterized by the fact that it involves more or less perfectly the tract for pain and temperature, and not for touch or muscular sense. Among twenty reported cases, I find hemianæsthesia affecting pain and temperature or else temperature alone in eighteen of the cases. Tactile anæsthesia, however, is occasionally present; it may be on the same side with the pain-temperature anæsthesia, or it may involve both sides. In two of my cases there was involvement of the temperature sense alone, and in one case this affected only the cold sensations. In one case the temperature anæsthesia, occurred upon the left side, while there was a temporary hemiplegia upon the right.

The usual motor-sensory syndrome in pons-medullary lesions, would be a hemiplegia, with pain-temperature anæsthesia upon the side of the paralysis, and muscular anæsthesia (ataxia), either upon the same side or upon the opposite side, more often the latter.

A good many cases are reported with anæsthesia of the face on the same side as the hemiplegia and anæsthesia of the body. Here the lesion must be in the upper half of the pons above the decussation of the cerebral tract to the trigeminus.

*Hemianopsia* is in rare cases observed in pons lesions. It would occur oftener, probably, if the posterior cerebral were not so readily supplied by blood from the posterior communicating. Besides,

pons softenings usually are due to lesions of the basilar near its origin from the vertebrals.

*Disturbance of deglutition* is due particularly to involvement of the deglutition center which lies in the motor root of the vagus (*nucleus ambiguus*). A disturbance of deglutition can be produced when only one side is involved.*

*Disturbances of speech* (dysarthria) are almost always present, and may be due not only to lesion of the vagus-glosso-pharyngeal nuclei, but to the upper motor path to these nuclei in the accessory lemniscus; also to injury of the root fibers of the vagus.* This nucleus sends motor fibers to the larynx. (Dees.)

Dysarthria is an important symptom when due to paralysis of the vocal cords, since the presence of such a palsy excludes pseudobulbar palsy.

*Vertigo* is a very common and often distressing symptom in pons and medulla lesions. It may be confounded by patients with the disturbance of equilibrium caused by lesions there, and often the two things go together. Vertigo of a very marked type is due, most often, to a lesion of the *corpora restiformia*, but it is also produced probably by lesions involving the nucleus and central paths of the vestibular nerve.

*Lateropulsion* or forced movements to one side, usually to the side of the lesion, occurs in lesions involving the *corpus restiforme*, the tract from the inferior olive to the cerebellum, or the middle peduncle of the cerebellum.

*Reflexes.*—If the motor tract is seriously involved we get an exaggeration of the deep reflexes, but in other cases, these are not particularly disturbed. Usually the abdominal reflexes are either feeble or abolished.

*Temperature, Pulse, and Respiration.*—The temperature is usually normal or slightly raised.

The pulse may be slow, but is usually irregular, and rapid.

The respiration, unless the lesion is severe, is usually not much disturbed. Disturbances of the respiration, temperature, and heart rhythm are due to involvement of the vagus and its nucleus. (Van Oordt, *loc. cit.*)

Paralysis of the larynx is due, according to Dees, to involvement of the central nucleus of the ninth and tenth nerves.

*Paralysis of the sympathetic* may occur in either pons or medullary lesions. It causes reduction of the palpebral fissure, slight retraction of the globe, myosis, reddening and, perhaps, sweating, on the side of the lesion.

*A systolic blowing sound* heard over the mastoid is sometimes heard in arteriosclerosis of the vertebral with aneurysmal dilatation as it passes into the basilar. This is due, according to Wallenberg, to stricture of the vertebral, causing increased pressure in the carotid.

*Pathological Anatomy.*—On this subject I have nothing new to offer and shall speak but briefly. The lesion is almost always an endarteritis, usually of syphilitic origin, but sometimes due to other causes and associated with alcoholism and nephritis and old age. In senile cases, like Case IV, there is only a very extraordinary degree of atheroma and senile thickening. Not rarely aneurysmal dilations are found on the vertebral or basilar arteries.

The following statistics show that the left side is more often affected. The basilar artery and the pons are slightly more often affected than the the vertebrals and the medulla. The *most common lesion* is a thrombosis of the vertebral with secondary thrombosis of the posterior part of the basilar. Thrombosis of the anterior basilar, as occurred in Case I, is very rare. I find notes of but one other case.

Simple senile softening of the pons, as in Case IV, is also very rare. I find one case besides my own. (Leyden.)

*Location of Lesion in Softening.*—The main seat of the lesion was: in the medulla, 13; in the pons, 19; in the pons and medulla, 7.

The lesions in the medulla were: on the right side, 5; on the left side, 8; in the pons, on the right side, 6; on the left side, 10; near the middle, 3. This shows an especial preponderance for the left side.

The arteries mainly affected were:

| | Right | Left | Total |
|---|---|---|---|
| Inferior cerebellar | 3 | 4 | 7 |
| Basilar | | | 12 |
| Vertebral | 1 | 7 | 8 |
| Both vertebrals | | | 2 |
| Multiple | | | 2 |
| Associated softenings in the cerebrum were observed in | | | 10 |

The basilar is usually soon involved by extension when a thrombosis occurs in the vertebral. The vertebral thrombosis may lead to thrombosis of the inferior cerebellar secondarily.

Embolism is very rare. Hallopeau and Leyden report cases.

*Comparison of Acute Hemorrhages and Softenings in the Pons-medulla.*—The medulla is rarely affected by hemorrhages.

Softenings affect the medulla and pons about equally; pons and pons-medulla softenings are twice as frequent as medulla lesions alone.

In non-syphilitic cases a lesion confined to the pons is rather more apt to be hemorrhagic than softening, especially if it be severe and occur in connection with nephritis and arterial sclerosis, whereas a lesion of the medulla is practically always a softening.

Both hemorrhages and softenings occur in men about twice as often as in women.

Softenings occur rather earlier in life than hemorrhages and are more frequent also in old age. Hemorrhages are relatively rare from fifty to sixty, while softenings do not drop off to the same extent.

Syphilis is a very much commoner factor in softenings, being present in over one-third of my cases, and probably is much more frequent than this percentage indicates. Arterial sclerosis, cardiac hypertrophy, and nephritis are the prominent causal factors in hemorrhage; the last two factors are rarely noted in softenings, except in extreme age.

We would expect hemorrhages, perhaps only capillary, in a bulbar paralysis developed in connection with pernicious anæmia, caisson accidents, status epilepticus, and child-birth.

Hemorrhages have usually fewer prodromata; the onset is more sudden and the conditions more severe, and the prognosis more serious. Twitchings and convulsive movements, profound coma, contracted pupils, and serious respiratory disturbances belong to hemorrhages rather than softenings. Hemorrhages occur almost entirely in the hard-laboring and hospital classes. Softenings are met with in all grades of society.

### PERSONAL CASES.

CASE I.*—*Syphilitic endarteritis and thrombosis of basilar artery, softening.*

*Van Oordt, *Deutsche Zeitschrift für Nervenheilkunde*, Vol. 8, p. 210.

*This case was examined by me and shown to my class. The notes and diagnosis were made by Dr. J. R. Hunt, who also made the histological examination and notes.

*Summary.*—Male, age thirty-two years. Prodromal headache and emotional irritability; sudden development of vertigo and left hemiplegia; later right hemiparesis; tremblings of limbs, forced crying and laughter, roaring in ears, dysarthria. Later complete anarthria, and glossoplegia, dysphagia, no sensory symptoms, temperature normal, pulse 120. Death. Autopsy: Thrombosis of anterior basilar and softening of anterior pons in its ventral part only.

[BY DR. HUNT.]

The patient, J. L., was a young man, aged thirty-two years, Canadian, cigarmaker by occupation, single, family history negative. He used alcohol in moderation, tobacco in excess. In January, 1899, contracted syphilis with mild secondary cutaneous manifestations and general adenopathy. Received seven weeks' dispensary treatment and all symptoms disappeared. In June, 1901, he became very much depressed, would burst into tears over trivial causes. At this time he also had headaches and was generally weak and run down. The headaches continued with intermissions and increased severity until December, 1901, when he was forced to discontinue his work for three weeks. One year before this his eyes had been so weak as to interfere with reading. He received internal treatment at an eye clinic, where he was told the affection was syphilitic in character. On January 18, 1902, while at work, he was seized with sudden weakness and vertigo and was unable to speak for half an hour. A few hours later he became completely paralyzed on the left side. This improved on the succeeding day, when the right side became paretic.

Was admitted to Bellevue Hospital, January 19, 1902, and walked into the ward, the left arm visibly paretic; while his bed was being prepared the left leg became completely paralyzed. He would burst into paroxysmal fits of weeping every few minutes. He complained of very severe headache and vertigo, roaring in the ears and some difficulty in articulation. Temperature 98.6° F., pulse 120, respiration 28. Urine negative.

Status on admission, January 19, 1902: Good physique, well nourished, moderately anæmic. Is in a very emotional state; in attempting to answer questions or perform simple acts consequent upon the examination he is subject to *spasmodic attacks of crying;* sometimes this weeping will be turned suddenly into laughter. There is general tremor involving the head, extremities and tongue, more especially on the left side. It is coarse, jerky, and irregular, not intentional in character, and resembles, but in a very exaggerated form, the tremblings accompanying a severe chill. His mind is clear and memory unimpaired. There is complete left-sided hemiplegia, including the lower branches of the left facial, and deviation of the tongue to the left. Marked rigidity with ankle and wrist clonus and Babinsky reflex on the left side. Skin reflexes are absent.

The right side is paretic; the tendon reflexes are exaggerated; Babinsky reflex present; skin reflexes present. Except for a moderate dysarthria, speech is unimpaired. The pupils are equal, all reactions present. Ocular excursions normal. Examination of thoracic and abdominal organs negative.

January 24. Sudden loss of power of speech. Could only utter inarticulate sounds.

January 26. Status: The patient is conscious and carries out simple orders. Pupils are equal and respond promptly to accommodation, feebly to light; ocular excursions normal; no nystagmus. Movements of the jaw are very weak and feeble, the mouth can only be partially opened. The tongue cannot be protruded beyond the teeth. Swallowing of liquids is accompanied with coughing and regurgitation through the nose. On attempting to swallow the larynx scarcely moves. Cannot articulate a single word; hears watch-tick on the right but not on the left. Incontinence of urine for twenty-four hours (inability to call). The right side is weak but the limbs can be moved. Ankle clonus present; no Babinsky. Pain sense is keen on both sides. Breathing is irregular in rhythm. Pulse is rapid and compressible.

January 27. Respiration rapid and shallow; pulse rapid and feeble; unconscious; died at 8 P.M.

*Autopsy.*—The basilar artery from its middle to the junction of the posterior cerebrals is converted into a white, rounded cord, the other vessels of the circle of Willis are normal to the naked eye. (Fig. 3.) The larger vessels arising from the basilar, *i. e.* the posterior cerebrals and the superior cerebellar, are

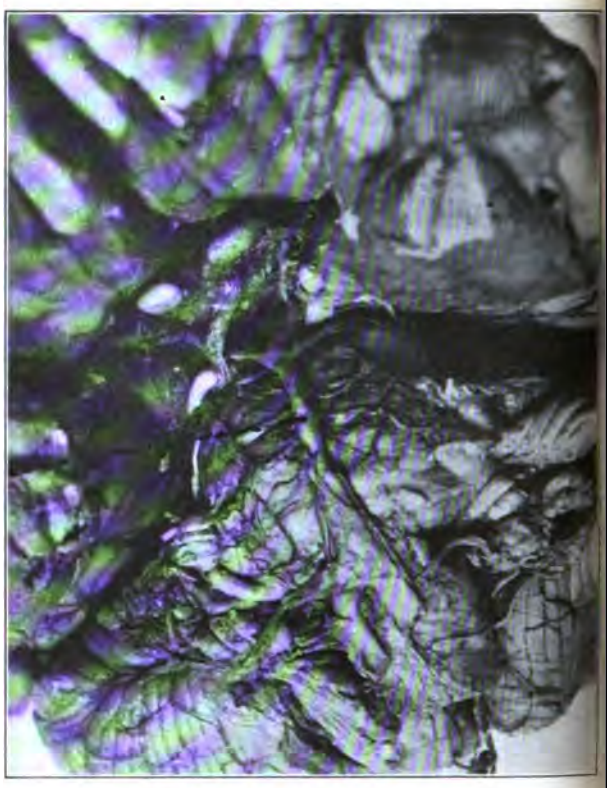

FIG. 3.—Base of brain, showing thrombosis of basilar artery.

distended with blood, but the walls are normal. There is swelling and softening of the pons on its basilar aspect, especially on the right side. Small patches of fatty degeneration on the intima of the thoracic aorta; heart normal; no hypertrophy. Old tuberculosis (healed) with adhesions at both apices. Hypostatic congestion of both lungs. The other organs, save for moderate congestion, are normal. No gummata found.

*Histological Examination.*—Serial sections were made of the affected portion of the basilar artery. There was a very high grade of concentric endarteritis and the lumen was almost—but nowhere completely—occluded. (Fig. 4.) It contained an old thrombus composed of fibrin, inclosing a few white and red cells. The thickening of the artery is essentially an endarteritis, but the media and adventitia are extensively infiltrated with round cells. In one portion of the adventitia extending into the media, is an area of necrosis with epithelioid but without giant cells (gumma). (Fig. 4.) The anterior cerebrals and middle cerebrals, save for a slight round-celled infiltration of the adventitia, are normal. The choroid plexuses contain many corpora amylacea, but the vessels are normal. The small central arteries of the thalamus and the cerebellum are

likewise normal. Transverse section of the velum interpositum shows round-celled infiltration of the adventitia in a few of the larger vessels.

Marchi sections of the cord show an absence of the secondary degenerations, the paralysis not having been of sufficiently long standing. In the upper half of the pons is an area of softening,

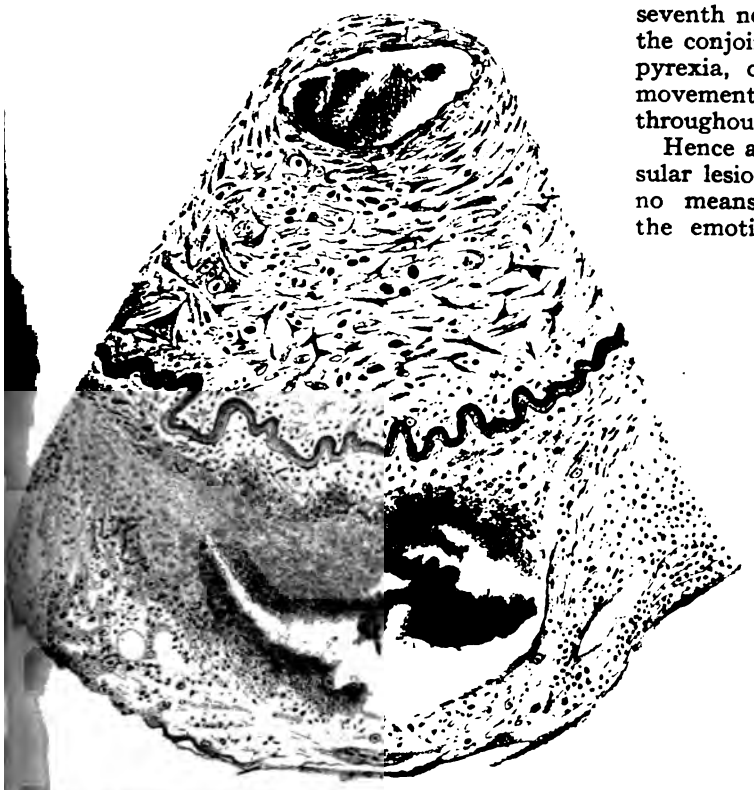

Fig. 4.—Section of basilar artery showing endarteritis, and small gumma of the adventitia.

greater on the right than on the left side, and situated in that portion traversed by the pyramidal tracts. The median and lateral fillet are untouched. The medulla and lower pons, save for a moderate round-celled infiltration of the pia and congestion of the vessels, are normal. There is one minute perivascular hemorrhage in the medulla. Nuclei of the cranial nerves are normal. (Fig. 5.)

The lesion extended upward to the upper limit of the pons, so that it could still be just seen on section made at this level. Below it extended to below the middle of the pons. There was no lesion in the cerebral hemispheres and cerebellum or the spinal cord.

*Remarks.*—Thrombosis of the cerebral half of the basilar artery is very rare. I find only one other case recorded, hence, in a measure, the peculiarity of the symptoms. Hemorrhages, however, are not infrequent in arteries branching from the middle and upper portions. The total anarthria would exclude a pseudobulbar palsy.

The case is of further interest in demonstrating that a complete occlusion of the anterior portion of the basilar may affect only the central portion of the pons. The cranial nerve nuclei and net fibers and the sensory tracts remaining intact. The collateral circulation received through the posterior cerebrals and the lower basilar evidently sufficed to maintain the nutrition of these parts.

The more characteristic symptoms of a positive lesion; as alternate paralysis of the fifth, sixth, and seventh nerves, conjugate deviation or paralysis of the conjoint movements of the eyes, myosis, hyperpyrexia, convulsions, sensory disturbances, forced movements, and oculomotor symptoms were absent throughout.

Hence a differential diagnosis from a double capsular lesion, *i. e.* a pseudobulbar paralysis, was by no means easy. The severity and constancy of the emotional outburst and the peculiar coarse general tremor, however, were in favor of a pons localization.

In view of the unusual findings in the medulla, the bulbar palsy must be referred to a lesion of the fiber-tracts in the pons carrying motor impulses from the cortex to the cranial nerve nuclei.

Case II.—Summary: Male, age forty-eight years. Emotional excitement, dysarthria and hoarseness, dysphagia; later delirium. Right side: some tactile anæsthesia, pain anæsthesia, some ataxia, slight hemiparesis. Left side: small palpebral fissure, marked ataxia of arm.

Autopsy: Thrombosis of left vertebral at junction with basilar artery. Softening in left pons. Small spot of softening in right medulla.

The patient was a steward on a steamer. He had always enjoyed good health, and was said to have been a sober and temperate man Three or four days before his admission to the hospital he was

Fig. 5.—Transection of pons, showing areas of acute softening, limited to the ventral and motor parts.

confined to bed and apparently very sick. He was occasionally delirious and complained of having a severe cold, having some difficulty in articulating, which was probably due to the beginning thrombosis. It was stated that he used to be a very heavy man, weighing over 200 pounds, but that he had, in the last six months, been reduced in flesh to 130 or

140 pounds. He had complained during this time of a partial paralysis of his left arm and of a cough. When the patient was admitted his mind was in such a condition that he could give no trustworthy account of himself. The appetite was fair, though he had some general bronchitis. He talked very hoarsely, as though there was some difficulty with the muscles of the larynx. When he drank anything, a little fluid entered the larynx, causing violent coughing.

Examination, made on his admission to Bellevue Hospital, February 28, showed a man quite stout, with some degree of conjunctivitis of the left eye. The left palpebral fissure was smaller than the right. There was no evidence of any marked paralysis of the arms or legs. There was some loss of pain and locality sense along the whole right side below the spine of the scapula; the contact sense is not diminished. There was also, on the right side, a marked ataxia of the leg, and the patient on this account was unable to walk unaided or to stand alone. There was, perhaps, with this ataxia, some motor weakness, but it was difficult to determine. On the left side there was a marked ataxia of the movements of the arm. There was, therefore, an ataxia and anæsthesia of cutaneous sensation for pain and locality upon the right side and on the left side marked ataxia of the arm. There was some little disturbance in articulation, and a distinct difficulty in deglutition; the larynx was not examined.

The patient became, in the next two or three days, delirious and excited. His ideas were extravagant, he always felt "first rate," and he had, to a certain degree, delusions of grandeur. The patient had no fever, pulse continued good, urine was high colored, acid, 1030, no sugar or albumin; the temperature ranged from normal to 99½, pulse was about 100. He died very suddenly on the morning of the fifth day after admission.

*Autopsy.*—The brain was congested, the meninges thickened and opaque. There was considerable bloody serum in the lateral ventricles. The membrane on the floor of the fourth ventricle was thickened. The arteries at the base were thickened and somewhat atheromatous. The basilar artery showed the presence of an aneurysm of the size of a pea at its junction with the two vertebral arteries; the vertebrals showed an endarteritis. The left vertebral artery was plugged, there was a softened spot in the left side of the pons extending to the middle peduncle of the pons and in the left side of the medulla near the dorsal surface; also a softened area in the posterior part of the optic thalamus; ependymitis of the lateral ventricles. The lungs showed spots of lobular pneumonia; the heart, fatty degeneration and atheroma of the aorta. There were some appearances over the front of the legs suggestive of syphilis.

The brain was lost before it could be further examined, but there were two lesions—one in the right pons and the other in the left medulla.

CASE III.—*Thrombosis and softening of right side of ventral pons.*

*Summary.*—Male, aged seventy-four years, no previous history; sudden left hemiplegia with some rigidity, face on same side involved. Emotional irritability, no forced laughter or crying, slight sensory disturbances. Softening in right side of ventral pons.

The patient, Orlando V., married, aged seventy-four years, U. S., was admitted to Bellevue Hospital on May 26, without any previous history except that he had been found suffering from hemiplegia. He was a large man, quite senile in appearance, but not emaciated.

The mind was clear, but he seemed rather childish and was restless and impatient, grasping his paralyzed hand and continually asking when he would get well. There was no dysarthria or trouble with swallowing. There was a paralysis of the left side of the body of the ordinary type, *i. e.* the lower face was moderately affected, the upper face hardly at all. The left arm was quite helpless, the leg somewhat less so, he could not walk but he could draw up the leg and move the arm a little. The eye muscles were not affected. There was some rigidity of the left arm and leg; the knee-jerks and elbow-jerks were lessened on the left and normal on the right. There was flexor response in the left foot, but not in the right. Epigastric reflexes not present. There seemed to be a very slight obtunding of cutaneous sensibility to pain on the left leg and arm. The urine had to be drawn with catheter. It had sp. gr. of 1020, albumin and hyaline casts. Pulse on admission 72. Respiration 20. Temperature 97⅕ F., rising next day to 99⅘. The heart was large and there was a slight systolic murmur at the apex. The arteries were hard. The pulse, however, of rather weak tension. The temperature continued 98° and 99° F. On the ninth day it was taken twice in each axilla.

Right axilla, 97.2—97.4; left axilla, 97—97.4, showing no essential difference.

The patient continued to become more restless; he complained of no especial pain, and did not have any fits of crying or laughing. He slept badly and had to be given morphine at times at night. He continued to grow weaker, his mind became more confused and dull. He passed fæces involuntarily. There was no change in his paralysis; no spasmodic symptoms developed. He died June 13 of exhaustion, eighteen days after admission.

*Autopsy.*—The vessels at the base were whitened and thickened with atheromatous changes to an extraordinary degree, but there was no complete obliteration of any of the vessels.

On palpation the right ventral surface of the pons was felt soft, and transections showed that there was a softened area involving the ventral part of the pons through nearly its whole length. The softened area was largest in the upper half of the pons where it involved the deep transverse fibers and the motor tracts and pons nuclei. The lesion became slightly smaller posteriorly, and at the level of the medulla the tissue was firm and apparently normal. The softening was limited entirely to the motor part of the pons and did not involve the superficial transverse fibers nor those of the trapezium. The softening was white and not so pultaceous as to fall out when sections were made. No specially obliterated vessel was found. On the corresponding ventral left half of the pons near a small recent hemorrhage about the size of a pea. The medulla was normal.

CASE IV.—*Thrombosis of pons, crossed hemiplegia, paralysis of left trigeminus and right half of body.*

Male, aged thirty-six, previous history negative, except that he had drank moderately and had been active in athletics. Denied absolutely ever having had syphilis. He suffered from eczema, and was treated for this by Dr. Geo. H. Fox, with whom I saw the case. In August he noticed a feeling of numbness upon the left side of the face, but this was not accompanied by any other marked symptoms. On November 30 he became a little dizzy and went to bed feeling well. Next morning he awoke paralyzed on the right side, in the arm and leg and on the left side of the face. Seen by me the next day, he showed a moderate facial paralysis of the left side, a marked paralysis of the right arm, less of the leg, and a complete anæsthesia of the left side of the face and left half of the mouth and

ongue as far back as the pillars of the fauces. he uvula hung straight. The muscles of mastiation on the left side were slightly affected. He ad some dysarthria, but no trouble in swallowing. here was some paræsthesia on the right side, but o anæsthesia, and no form of objective sensory isturbance. There was no loss of sense of taste the anæsthetic side of the tongue, and no aparent disurbance of mucous or salivary secretion. he left eye showed slight myosis.

The patient gradually improved, but a month ter he had another slight attack of hemiplegia, ttacking mainly the left arm.

Case V.—*Crossed hemiplegia; paralysis of left facial and right side of body, with anæsthesia.*

Sebastian K., aged sixty years, German. The paent was admitted to Bellevue Hospital without prelous history. The patient had the marks of adanced senility; his mind was dull, and had some fficulty in speech. There was complete parysis of the right upper extremity, partial parysis of the right lower, and total paralysis of e left side of the face. The skin reflexes were sent on the paralyzed side; deep reflexes present. nsation to pain was diminished on the paralyzed e. Patient became more and more apathetic, d suffered from incontinence of urine and fæces; d-sores developed. Death; no autopsy.

Case VI.—*Cerebral syphilis, thrombosis of branch right vertebral, right hemiplegia, thermoanæsthesia, ralysis of left vocal cord. Later general paresis.*

C. H., aged thirty-nine years, married. The tient had always been a strong, vigorous man, t he had indulged in alcohol a good deal, and d been infected with lues eight years before I w him. About a year before my examination of n he had an attack of right hemiplegia and right rmoanæsthesia, with a paralysis of the arytenoids, that he had some difficulty in speech. The ent was sent to me by Dr. Holbrook Curtis, o made an examination of the larynx, and furhed me with this diagnosis. The laryngeal ralysis was on the left side. He recovered enly from the hemiplegia, and when I saw him d simply a loss of the heat and cold sense upon e right side of the body; some of the laryngeal ralysis was still present; no ataxia. There were ggerated reflexes, but no ankle clonus or exsor response of the toes. In other words, the ects of his attack were nearly gone. It was evit, however, that he had a slight softening in the side of the medulla. He subsequently developed resis and died in about two years.

Case VII.—*Summary:* Male, forty years, syphilis incient tabes. Sudden development on *right side:* of ataxia, tile anæsthesia, analgesia of lower face, paræsthesia of t, paræsthesia of cold in lower face, slight hemianop-; no paralysis. *On left side:* analgesia and thermoesthesia; paræsthesia of cold; no cutaneous anæsthesia; paralysis; no dysarthria or dysphagia; no lateropulsn. Lesion probably in lower half of left pons.

The patient had a luetic infection at the age of enty; for the past five years he had suffered from htening pains in the legs; for one and a half years e bladder had been slow. A year ago he had an ttack of grip followed by left facial herpes. About me months before I saw him he had an attack of ght hemitaxia, with no disturbance of speech or ss of consciousness, or difficulty in swallowing. le was obliged to remain in bed a month on account f awkwardness of the right side; along with this disurbance on the right side, he had a loss of pain sense n the left side and over a spot on the right side of he chin. His condition of analgesia and ataxia mproved, but he suffered from subjective sensaions of heat on the right side and of freezing cold ain over the left side of the face.

When seen by me he had rigid pupils and a slight right hemianopsia, which he said came on at the time of his attack. The knee-jerks were exaggerated. He had lightning pains and the visceral weaknesses of posterior sclerosis. Physical examination showed him to be a person in good general health, able to walk fairly well, with no hemiplegia or motor paralysis. There was ataxia of the right side, shown by inability to place the finger at a definite point or recognize the position of the limbs, but there were no forced movements. He had, at the time of his attack, some right tactile anæsthesia, but never any motor paralysis. There was anæsthesia to heat and cold on the left side of the arm, trunk, and leg and slight analgesia over the same area; also an analgesic spot on the right side of the face in the distribution of the inferior branch of the fifth nerve. He had allochiria, that is, on pinching the left side of the body, he would feel it on the right side, at a corresponding point. His right hemianopsia appeared more marked in damp weather and when he was tired. The ataxia was only moderate. He could use the hand clumsily, could put the finger fairly well to the tip of the nose, recognize weights and the position of the limb, and it was mainly a defect in motor coördination. He has the Brauch-Romberg symptom, but could stand with the eyes closed and feet wide apart. There was a slight tremor in the right hand. His left thermoanæsthesia was absolute. Even freezing solutions cause only pain and hot things the same. He had a slight analgesia on the left side, and he did not feel a strong electric current. Coördination of the left side wss perfect. He had had no disturbance of speech, of deglutition or of the tongue. He had a drooping of the right lid, but the ocular movements were normal. There was some tickling and paræsthesia of the left side of the face where he once had herpes. The left pupil was larger than the right, but reacted to light. He had a hyperhidrosis of the left hand.

I infer that this patient must have had a thrombosis affecting the medulla, involving the median and outer lemniscus and parts external on the left side.

Case VIII.—Female age fifty-two years; two healthy children. The patient had been subjected to much worry for the past two or three years. Habits good, no infection. One week ago had a very severe headache; late in the day, slight ptosis. Walked home and went to bed. In two days this was nearly well. Then the ptosis returned with involvement also of the left eye and thickness of speech, but no hemiplegia. She again went to bed and gradually became semi-comatose. In the last two days she had Cheyne-Stokes respiration.

When examined by me the patient was in bed, unconscious, though she could be partially roused at first. She put out her tongue and moved her hands, arms, and legs fairly well and coördinately. She had Cheyne-Stokes respiration. Pulse 106, regular. She had complete double ptosis. Both pupils were dilated and did not react to light. The right eye turned out, the left was straight. All ocular movements paralyzed. All other cranial nerves seemed normal, except that she had difficulty in swallowing and that her speech was thick. Knee-jerks were exaggerated; slight clonus, more on right. Babinsky present on both sides. Epigastric reflexes gone on both sides. No anæsthesia. The patient died three days later.

Case IX.—*Syphilitic endarteritis and thrombosis of branch of upper basilar, right hemiplegia, thermoanæsthesia, with some ataxia of left arm.*

Male, aged forty-four years, lived an active life,

participating in outdoor sports, and had always been temperate. About eight years before I saw him he had an infection which was thoroughly treated. Six months before I saw him he had a slight attack of hemiplegia on the right side, with thermoanæsthesia of the left side. There was also a slight ataxia of the left arm.

When seen by me he still had some traces of the right hemiplegia, but could walk fairly well. There was still complete thermoanæsthesia of the left side, and a very slight trace of ataxia in the left arm. No hemianopsia. He subsequently suffered for one or two years from general symptoms of arterial sclerosis of the brain, but gradually improved. He had at times a slight right hemianopsia. Thus the symptoms were: Right side, hemiplegia (temporary). Left side, thermoanæsthesia (permanent); slight ataxia (temporary).

## ABSCESS OF THE LEFT TEMPOROSPHENOIDAL LOBE OF OTITIC ORIGIN; OPERATION; RECOVERY.*

BY E. GRUENING, M.D.,

NEW YORK.

THE symptoms which led to the diagnosis of abscess of the temporosphenoidal lobe in the patient under consideration were rapid development of choked disc, slow pulse rate, intense headache, and vomiting. The important localizing symptom of abscess of the left temporosphenoidal lobe, amnestic aphasia, was absent before the operation, but appeared immediately after it. Other interesting features of the case were (1) the discharge of pus from the abscess cavity followed by the flow of a clear watery fluid, evidently ventricular; (2) the rapid recovery of the patient in spite of the communication of the abscess cavity with the ventricles of the brain.

J. K., aged seventeen, an Austrian by birth and furrier by trade, was admitted to the Mt. Sinai Hospital on April 15, 1903. He complained of pain behind the left ear. During the past three days he had had several chills. Both ears had been discharging a long time, and the left ear always more than the right. On admission he suffered from frontal headache and photophobia. The left mastoid region was tender on deep pressure and the corresponding middle ear was filled with granula-

*Read at the meeting of the American Otological Society at Washington, May 12, 1903.

tions and cholesteatomatous masses. The attic of the right ear was also diseased. Temperature 104°, pulse 92, respiration 28. Examination of the lungs, heart, liver, spleen, and abdomen gave negative results. The pupils were small and equal and reacted well. Ophthalmoscopically the optic discs appeared somewhat swollen, redder than usual, and the retinal veins were dilated and tortuous.

Operation, April 15, 1903. Nitrous oxide and ether anæsthesia. Usual incision for the radical operation with an additional cut 3 cm. in length at right angles posteriorly. Entire mastoid exposed. Cortex hard and apparently healthy. Interior of mastoid down to the apex, diploic in structure and softened. The supero-posterior wall of the external auditory canal had disappeared—the radical operation had been performed by nature. The tympanic cavity was filled with granulations, the antrum packed with cholesteatomatous material. The sigmoid sinus was far forward, only 4 mm. from the external auditory canal and surrounded by diploic cells. The emissary vein was likewise imbedded in softened diploic bone structure. The sigmoid sinus and the emissary vein were laid bare. The upper knee of the sinus was covered with a thin grayish exudate, while its other parts and the emissary vein presented the normal blue appearance. The cholesteatomatous masses were removed from the antrum and the granulations from the tympanic cavity. No ossicles and no tympanic membrane were found. The antrum, very large, size of a filbert, showed a perforation through its roof. The opening measured 1 cm. in diameter. The dura mater, prolapsed into the antrum, was covered with hard granulation tissue. In the tympanic roof a small spot of discoloration was seen. The opening in the antral roof was enlarged by the removal of bone, including the discolored area in the tympanic roof. In the dura mater no other changes save those mentioned above were found, and no pus was encountered in the cranial cavity. A small erosion was discovered in the bone over the horizontal semicircular canal.

At the termination of the operation, which lasted over one hour, the wound was irrigated with sterile salt solution, flushed with absolute, alcohol, and dressed with iodoform gauze.

April 16.—Temperature still 102.8°, pulse slow, 70 to 80.

April 17.—Temperature 101°, pulse 80; general condition much improved.

April 20.—Temperature 98.6°; general condition good. Soft diet.

April 22.—Vomited this morning. Severe frontal headache. Photophobia. Optic discs red and swollen. Wound looks well. Temperature 99° to 100.4°. Pulse varying greatly in frequency, 48 to 84.

April 24.—Still complains of headache, but takes nourishment. No focal symptoms. No amnestic aphasia. Temperature 98° to 100.4°. Pulse 54 to 76. No vomiting. Late in the evening of the 24th the patient began to moan and said that his headache was unbearable. Ophthalmoscopic examination showed marked double optic neuritis (choked disc); sensorium clear.

Operation, April 25. Nitrous oxide and ether anæsthesia. Wound curetted, irrigated, and treated with absolute alcohol. Incision 1½ inches upward, exposing squama. Temporal ridge and portions of squama, tympanic, and antral roofs were completely removed. The exposed dura was thoroughly cleansed with absolute alcohol. Aspiration through under surface of brain in region of the tympanic roof. The needle was carried one inch upward and one syringeful of thick pus was obtained. A crucial incision through dura mater and the under surface of brain was then made and gave exit to about two ounces of thick yellow pus. Finger introduced into the brain could feel a limiting membrane. No irrigation of brain abscess. Drainage by narrow selvaged strips of iodoform gauze. Wet dressing. During the operation the pulse rose from 64 to 100.

April 26.—Marked amnestic aphasia, which did not exist before the operation. The patient could not name objects shown to him, but described their use in fluent language. Temperature 101.2°, pulse 60. Slight headache. Pupils equal. No taches. No rigidity of neck. Reflexes normal.

At the dressing of the wound, the withdrawal of the gauze was followed first by a discharge of pus, and then by a flow of a considerable quantity of clear watery fluid. After the dressing the pulse rose from 60 to 88. The symptom of aphasia was less apparent, the patient naming several objects but tiring after a few questions. Choked disc still pronounced on both sides.

April 27.—Temperature 99.4°, pulse 86. General condition improved. Aphasia less marked; patient could name several objects. At the dressing, pus and watery fluid evacuated from brain abscess.

April 28.—Temperature 99.2°. Pulse 96. Patient feels well. Good appetite. No aphasia. No retention of pus. Left pupil larger than right. Choked disc still present.

The patient made a rapid recovery and was presented at the May meeting of the New York Otological Society.

36 East Fifty-seventh Street.

## THE RATIONAL TREATMENT FOR MOUTH-BREATHING.

By W. H. FITZGERALD, M. D.,
LARYNGOLOGIST AT ST. FRANCIS HOSPITAL,
HARTFORD, CONN.

That nature intended man for all climates is unquestioned, but if man live other than nature intended he should he must be content with dire consequences so far as health is concerned. And why is it that certain individuals enjoy better health in certain climates than in others?

To my mind the reason in a majority of cases is that they are mouth-breathers and bear better the mild than the severe climate.

Who are afflicted with chronic nose, throat and chest affections? The mouth-breather always, and we will never stamp out such conditions as pulmonary tuberculosis, together with numerous other affections of the respiratory tract, until we—the human family—have learned to take every inspiration through the nose.

I have taken the liberty to divide mouth-breathers into two classes, confirmed and moderate. The *first* breathes almost continually with open mouth. The *second* is not conscious that he breathes other than through the normal channels and will not admit that he does otherwise until you convince him such is the case. It is my custom to engage the doubting one in conversation or have him read for me, when he will be surprised to learn that he has spoken several sentences or read many paragraphs without once closing his mouth. He it is who after lecturing or reading aloud, or perhaps singing, is dry of mouth and husky of speech and wonders why.

*Treatment:* Restore the nose to as nearly a normal condition, physiologically speaking, as possible, and then insist upon your patient using it. So long as the spray, douche, and solution treatment generally are patronized just so long will we fail to

get good results, for, as Dr. Leland remarks, the nose wants air and not water.

Douching and spraying are contrary to nature and should never be practised.

Solutions in the nose seldom cure, and are very often excitants, not only to the nose, but to the accessory cavities and ear. Every inspiration taken through the mouth is at the expense of the nose, favoring hypertrophies, and thus causing anomalies of the respiratory and adjacent tracts.

When the patient is a mouth-breather through habit, and this may be determined by having him breathe first through one nostril and then the other, it is my custon to order him to breathe forcibly through his nostrils at the rate of one respiration per second for ten seconds, this to constitute one exercise, to be repeated often, perhaps eight or ten times during the day. He will find that this more than compensates for his spray, for having used the spray in the morning he is "filled up," as he expresses it, long before noon. His nose he can exercise at will and thus keep it free. The exercise I prescribe for all patients during the process of repair following operations, to be continued until they are confirmed nasal-breathers. A mouth guard should be worn at night for a few weeks. In my practice the most satisfactory form of mouth guard has been a small strip of adhesive plaster (fine oxide lined) worn vertically across center of mouth.

If we are going to cure nasal catarrh and other respiratory difficulties, the respiratory tract being freed of all obstructions and irritable areas, the patient must be taught to breathe normally.

Irritable areas are not always detected by the probe, therefore we cannot depend upon that method, but must note that these patches have a characteristic appearance. They are found not only in the nose but ofttimes in the nasopharynx and pharynx as well, and are of a pale, water-logged appearance. They may be obliterated surgically or by cauterization, and if the nose thereafter is properly used like areas do not return. This may be said for all hypertrophic removals. To bring about a permanent patency of the eustachian tube the individual must become a nasal-breather, therefore it is absolutely essential to overcome or permanently improve most varieties of deafness and tinnitus aurium that the patient breathe through the nose at all times. The eustachian catheter is often harmful, acting as a mechanical irritant, and thus assisting the progress of an already thickened and, perhaps, irritable membrane.

The dilatation of the cheeks of the patient, and the inflation, perhaps for the first few treatments, of air medicated and thereafter occasionally with air in its purity, or Professor Politzer's method, the patient being careful between times to continue his breathing exercise, are vastly superior to other forms of inflation. Air is what the thickened eustachian orifice needs to return it to a normal state, and this applies to the thickened or collapsed eustachian tube and middle ear as well, also the accessory nasal cavities.

The oxygen treatment is familiar, but why use oxygen artificially when air breathed normally will supply it?

Your patient can go to a milder climate and breathe with open mouth and be benefited, but would it not be far better for him to remain at home, breathe through his nose and fully recover?

Commence with the babe. Make it a special point that it breathe through the nose. If it cannot, know the reason why. Certainly if the Indian mother recognized the necessity and insisted that her babe breathe properly, the civilized mother of to-day should. Follow it from babyhood to childhood; impress the necessity upon it as a child and, barring accident, it will never breathe otherwise. If it is found, following an accident from fall or blow, that the nose is not free have the fault corrected. Normal breathing will help materially to bring about perfect development, and without normal breathing such development cannot be attained.

---

## THE INTERNAL ADMINISTRATION OF METHYLENE BLUE AS AN AID IN THE DIAGNOSIS OF URETHROPERINEAL FISTULA.

By RICHARD LIGHTBURN SUTTON, M.D.
ASSISTANT SURGEON, U. S. NAVY.
U. S. NAVAL HOSPITAL, WASHINGTON, D. C.

THE injection of certain staining solutions into the various canals and hollow viscera in order to determine the presence or absence of abnormal openings has been successfully practised for years, but it is seldom that one finds a drug given by the mouth, with the intention of causing a marked coloration of some particular excretion, thus bringing to light any sinuses or fistulæ which may exist.

The following case will serve as an illustration: T. J. L., white, twenty-eight years, admitted to hospital April 17, 1903, suffering from perineal abscess. He was treated for abscess in the same location about one year ago. He has had several attacks of gonorrhœa, and there is now a slight purulent discharge. No history of complete stricture or retention of urine. A No. 20 French sound was passed, but a contracted external meatus precluded the use of a larger size.

The abscess was incised, under cocaine anæsthesia, a few hours after the patient was admitted. Careful examination with a fine, blunt-pointed probe failed to reveal the presence of a suspected communication with either the rectum or genito-urinary tract. There was no swelling, œdema, pain, or tenderness in the region of the triangular ligament, and the urine was passed freely and without apparent effort, consequently infiltration from a ruptured bladder or urethra was considered improbable. No abnormal openings leading into the rectum or anus could be discovered.

The wound was dressed with plain, sterile gauze, and capsules containing methylene blue and oleum santali were ordered for the urethral inflammation. When the dressings were removed on the following morning it was noticed that the material was stained a light indigo color. This led to a closer examination of the urethra, and the remains of an old annular stricture were found just anterior to the membranous portion.

To render the diagnosis positive and to clear up all doubt as to the condition present, the external wound was thoroughly cleansed and a small protected gauze pad was applied and secured snugly in place by means of a T-bandage, while the internal medication was continued. The dressings were removed late in the evening, and were found discolored as before, although the patient experienced no difficulty whatever in passing the normal amount of urine through the natural channel.

The stricture was gradually dilated by the use of sounds in the usual manner, until the channel was practically normal in size. After the first week the discharge of urine through the sinus entirely ceased, but the external wound was kept open for some time, by means of gauze packing, in order to prevent the formation of a pocket.

This method of diagnosis is particularly applicable to those cases in which a fistula communicating with the genito-urinary tract is suspected, or

when the connecting channel is so tortuous and irregular as to prevent the passage of a probe. Its simplicity, reliability, and freedom from pain certainly recommend its trial in these cases.

## A POSSIBLE CASE OF INFANT POISONING AS A RESULT OF ABNORMAL MENTAL AND PHYSICAL CONDITION IN THE MOTHER.

By CHESTER J. STEDMAN, M.D.,
FORT ADAMS, NEWPORT, R. I.
CONTRACT SURGEON U. S. ARMY.

HENRY W., a rather large, well-developed baby of seven months, had, previous to the following incident, always enjoyed good health. He had been nourished from birth, entirely from the mother's breast.

On Saturday, June 27, 1903, the child nursed, as usual, about 4.30 A.M. About 7 A.M., as his mother was again preparing to give him the breast, he suddenly stiffened out and became practically unconscious; the spasm lasted for only a few moments, but seemed to leave the child in a more or less dazed condition. About 8.45 A.M. he had another spasm, or convulsion, similar to the first, and passing away quite as rapidly. About fifteen minutes after the second convulsion, the child's bowels moved; the motion consisting of about the normal amount of semi-solid fecal matter, but containing, also, a considerable intermingling of blood. Immediately following the movement of the bowels, vomiting took place; the vomited matter being slight in amount, and having the appearance of slimy water; but containing no blood. About 11 A.M. there was a second movement from the bowels, less in amount than the first; but containing, also, a slight amount of blood. The amount of blood in either motion was not large.

I first saw the child about noon. Beyond a slight apathy, he had every appearance of a normal child. There was no temperature, and he gave no signs of distress. The mother showed me the last stool, which she had saved; although mostly absorbed by the napkin, it still showed unmistakable evidence of having contained a slight amount of blood. I gave the child a small dose of paregoric, and requested that I be immediately sent for in case he should become worse.

On Sunday evening I saw the child again, at which time he appeared perfectly well. The mother told me that the only symptom of trouble he had shown, since Saturday morning, was another blood-tinged motion from the bowel, which occurred about 6 A.M. Sunday; this motion being larger, and containing more blood, than either of those of the previous day. The child's bowels moved twice more on Sunday; but the motions, which were slightly watery, contained no blood.

To the best of the mother's knowledge, the child had taken absolutely nothing but breast milk into its stomach.

The major part of the foregoing account is given practically as it was told me by the mother. She further told me that, on Friday morning, she had felt it necessary to take a dose of salts; but that, contrary to custom, the salts had produced no effect, her bowels remaining unopened all day. She also told me that she had been very much worried, on Friday, over some household matters.

The case is submitted, not as absolute evidence, but, rather, as suggesting the possibility that the digestive disturbance of the breast-fed infant may have been secondary to the aforementioned physical and mental condition of the mother.

## A CASE OF SMALLPOX IN THE FŒTUS.

By J. H. FRANKLIN, M.D.,
SPRING VALLEY, ILL.

W. M., an American, aged thirty-two years, became ill on the evening of March 1. A physician was called on March 3 and the typical eruption of smallpox appeared on March 4. The family, consisting of the wife and three children, were vaccinated on March 5. Mr. M.'s case ran the typical course of variola.

Mrs. M., of German descent, aged twenty-eight years, was seven and a half months pregnant at the time her husband was attacked. She had had one miscarriage two years previous to this time. She claimed she had never been vaccinated, although, having been born in Germany, she may have been vaccinated when an infant, but no scar was visible. Five days after the first vaccination she was vaccinated again, successfully. During the time of the quarantine, which was until April 1, Mrs. M. complained of no constitutional symptoms whatever and there was no skin eruption of any kind. Two weeks following the raising of the quarantine, or on April 14, she began to have labor pains, and on the afternoon of that date was delivered of a full-term child with the typical eruption of smallpox in the pustular stage. The lesions on the child were large, at least a quarter of an inch in diameter and deeply umbilicated, and while very numerous, were discrete. The child had evidently been dead for several days, as it was slightly macerated. The mother made an uneventful recovery, no rise of temperature occurring, and she was up on the tenth day.

This woman never complained of constitutional symptoms of any kind, for which reason it is extremely improbable that she had variola without eruption.

**Enlarged Tonsils a Cause of Middle-ear Catarrh.**—C. P. Linhart says that when the tonsils are of abnormal size the patient is subject to frequent colds with acute inflammation of the tonsils and other lymphatic glands, and when the surrounding tissue is hyperplastic, the additional swelling of the glandular tissue increases the obstruction to the opening to the eustachian tubes, leading to disturbances in the eustachian tubes and middle ear which occasionally produces a purulent inflammation of the middle ear. The author reports two illustrative cases. Removal of the tonsils improved the hearing.—*Columbus Medical Journal.*

**Report of a Case of Tonsillar Ulcer of Vincent.**—Lawrence J. Royster describes the case of a child with normal pulse and temperature, and apparently no indisposition beyond pain on swallowing. The lymph nodes at the angle of the jaw on the right side were greatly enlarged; on the right tonsil there was a patch of grayish deposit, nearly as large as the tonsil, slightly depressed and having a very ragged outline. The edges were redder than the normal color of the tonsil, and on removing the membrane, or rather slough, which came away without resistance (but had a great tendency to reform rapidly), the ulcerated and bleeding base of the lesion could be seen. The tonsil was hard and indurated. The diagnosis from diphtheria was made from the normal general condition, and marked tendency to chronicity. The diagnosis from syphilitic ulcer was difficult, but as the patient was only seven years old the author dismissed it from his mind, and Vincent's ulcer occurring to his mind, he made a smear from the edge of the ulceration, stained it with dilute carbol fuchsin, and then found the fusiform bacillus and spirillum of Vincent. Treatment consisted of hot gargles of normal salt solution, and tincture of iodine applied locally. The ulcer had entirely disappeared three days after treatment was instituted.—*Archives of Pediatrics.*

# MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

## THE PRESENT POSITION OF SUTURE OF THE BLOOD VESSELS.

UNDER this title Dr. Arthur H. Burgess gives, in the *Medical Chronicle* for May, 1903, a critical review of this subject, citing in abstract the published cases and the technique resorted to. His main conclusions are: The opinion appears to be steadily gaining ground that, whenever possible, wounds of the larger blood vessels shou d be treated in such a manner that healing of the vessel wall may take place without the lumen of the vessel becoming occluded during the process, and several successful instances of this have now been recorded, more especially in connection with the large veins. The two chief procedures advocated for this purpose are (1) lateral ligature of the vessel, and (2) direct suture of the wound in its wall, the former being advisable only in punctured or small incised wounds, and only in connection with the veins, whilst the latter is of much wider applicability. . . . Arterial suture being as yet only in its infancy, it is impossible to establish its precise indications and limitations, or the exact technique of its performance. It is only applicable to the larger arteries, and is especially serviceable whenever there is reason to fear that ligature of the vessel might possibly result in gangrene. The arterial wall must be in a healthy state, and the wound must run an aseptic course. Moreover, it must be possible to control the circulation, both proximally and distally, at a distance from the wound sufficient to allow of the necessary manipulations. This control may be applied digitally or by rubber-padded clamps, such as those specially introduced by Crile (*Annals of Surgery*, April, 1902) for the temporary closure of the carotid arteries. Great care should be exercised that the pressure does not injure the endothelium, and on this account temporary ligature is not advisable. Cleanly incised wounds and those in a longitudinal direction are the most favorable for suture. If the edges are much lacerated that portion of the artery should be excised, if not too extensive, and the continuity restored by Murphy's method of invagination. This procedure is also to be utilized whenever a transverse wound involves more than one-half of the circumference of the artery. Fine silk forms the best suture material, and should be threaded on ordinary domestic sewing needles of as small a size as can be conveniently handled. The suture should take up the two outer coats only, and may be an interrupted (twelve to sixteen to the inch) or a continuous one, preferably the latter. When the suture is completed the distal clamp should be removed first, allowing a reflux of blood which will test the efficiency of the sutures before they are exposed to the full force of the blood-stream. The sheath of the artery should be carefully sutured, so that it may form a barrier against sepsis should the wound suppurate superficially. The risk of the subsequent development of an aneurysm at the sutured site appears to be very slight, and no instance of it has yet been recorded, either in the human subject or in the numerous experiments on animals. It is probable that in the invagination method the proliferation of endothelium ultimately occludes the vessel entirely, but in the meantime the collateral circulation will have sufficiently established itself to prevent any consequent ill effect.

The authors then cite Matas's operation upon aneurysmal sacs (*Annals of Surgery*, February, 1903) as a recent extension of work along this line. The circulation being controlled proximally (and, if necessary, distally also), an incision is made in the long axis of the sac, the clots are turned out, and the mouths of all vessels entering the sac are exposed. These orifices are then closed from within the sac by entering a full curved needle carrying chromatized catgut sutures, one-quarter to one-sixth inch beyond the margin of the orifice of one side, the needle then reappearing at the margin, re-entering at the opposite margin, and finally reappearing at a corresponding distance beyond, taking a firm hold of the endothelium and underlying fibrous tissues during its passage through either side. In the sacculated aneurysm the single orifice is sutured similarly, care being taken not to encroach upon the lumen of the vessel. Upon relaxation of the compression there should be no leakage at the point of suture. Where there is abundant material a second row of strengthening stitches is passed and the skin then turned in to obliterate the cavity, after the manner of obliterating bone cavities by cutaneo-periosteal flaps. Matas has treated four patients in this way. He suggests (but has not actually carried out) the restoration of the arterial channel of a fusiform aneurysm by stitching the edges of longitudinal elliptic excisions, moulding the new vessel wall upon an inserted rubber tube, which is withdrawn just before the last stitches are taken at the center of the incision. Concerning suture of the veins the author remarks that it is interesting to note the terror of the pre-antiseptic surgeon caused by a wound of a large vein, and how the fear of gangrene was ever before him when he ligated. Indeed ligature of the femoral artery was generally recognized as the correct practice in case of a wound of the femoral vein. Still even before antiseptics some surgeons ligated large veins without gangrene, and since the introduction of antiseptics this procedure has become devoid of danger. Indeed, the inferior vena cava has been ligated three times with two recoveries. A more ideal method of treatment, however, is that of closing the wound without obliterating the vein by lateral ligature, lateral application of forcipressure forceps, or suture of the wound. The circulation being temporarily shut off, interrupted sutures of fine catgut or silk are passed with a full curved needle, not more than three or four millimeters apart through all the coats of the vessel. Over these a second row is passed, taking

up the cellular sheath and the surrounding connective tissue. For suture to be practicable the wound must be linear, not too extensive, and in the long axis of the vein. Following the suture, a small parietal thrombus forms which scarcely encroaches on the lumen, and which becomes covered by endothelium and organized, so that ultimately a firm cicatrix is formed. Henzel prefers suture to lateral ligature as encroaching less upon the lumen, giving a surer guarantee against secondary hemorrhage, and involving less risk of embolism. Recent experiments upon animals have also demonstrated the feasibility of the establishment of anastomosis between two contiguous veins (*e. g.* the portal and the cava), and also the establishment of an arteriovenous anastomosis. In neither of two reported cases, however, did the established anastomosis between the femoral artery and vein operate to arrest the precedent gangrene. At the autopsy on one of the cases the orifice of anastomosis was found patent, but greatly reduced in size. Jaboulay has suggested the invagination of the proximal end of a divided artery into the distal end of a vein in conditions of defective cerebral circulation, but it has not yet been practised. Experiments on the cadaver have shown that fluid injected into the peripheral end of the divided internal jugular was promptly returned by all the deep and superficial veins of the head and neck, but in the limbs it was impossible to overcome the resistance offered by the valves. Still, in arteriovenous aneurysms the pulsation is sometimes transmitted rather far down the vein, so that the valves probably yield somewhat to prolonged pressure. Possibly, too, in advanced life they are somewhat more patent. Nevertheless the evidence in favor of the value of the establishment of arteriovenous anastomosis for the relief of endarteritis obliterans is not convincing.

## THE BASIS OF LIFE.

THE more or less identical questions of what life in its narrow sense is and what is its physical basis are just now exciting some discussion in both the scientific journals and the newspapers. The question has never been in abeyance since the promulgation of Darwin's law of evolution, that is, among scientific men; but it is only recently that the lay press has appreciated the usefulness for its purposes of a more or less sensational discussion of electricity, ions, protoplasm, and other terms with the significance of which its writers express such perfect familiarity. There is even a tendency among laboratory workers and scientific theorizers to announce generalizations and to give to the world what the observer would like to believe or to prove, in marked contrast with the work of some of the patient accumulators of facts of a generation ago. This is an undesirable state of affairs, since it gives an exaggerated value to facts already in our possession, and a distorted view of our proper lines of investigation in the future.

In discussing a subject like the present one, it is absolutely necessary that there should be an accurate conception of the meaning of the terms used. If this rule is observed such redundant expressions as "ultimate atom" will not be met with, and the question as to what "life" is will be one of physiology and chemistry, cleared of all psychological and poetical verbiage.

What we really know on this subject is much, and it is little. We know that the typical cell is formed from protoplasm, which is a substance composed of highly complex organic matter, and that under a favorable environment this protoplasm will manifest properties which clearly depend upon the integrity of some so far undiscovered atomic arrangements, for when the environment becomes unfavorable, and the atomic arrangement is changed, the protoplasm ceases to show evidences of "life" and is broken up into a number of less complex substances, many of which are easily identified. The active process exhibited by such protoplasm and commonly called "the vital process" or life is frequently alluded to as "mysterious" when something supernatural is meant. The process is mysterious, but it is not supernatural, and there is absolutely no reason to suppose that it depends upon any psychical, spiritual, or supernatural influence, force, or afflatus to which the protoplasm may be subjected. The quality of mystery depends upon our inability at present to understand the finer chemical and physiochemical relations of the atoms in complex bodies like protoplasm, and the laws which govern alterations in such relations. Our ignorance in this regard is not hopeless, if we can judge by the enormous advances of the past two decades in organic chemistry, especially in the department of synthetic work. Another difficulty in the use of terms is that caused by the limitations of the human mind, which in forming any conception in an abstruse subject always personifies something, though unintentionally and unconsciously, and refers everything to mental processes which are glorified and exalted counterparts of its own activities. In other words, the human mind cannot conceive of an impersonal universal force without looking for some, at least, of those qualities which make all human minds more or less circumscribed psychological arrangements.

Another law which we have formulated in our study of cellular processes is that activity in cells is in general proportional to their chemical and physiological complexity, and it is a reasonable inference that there is an ascending scale of physiochemical activity, at least in organic substances, until such a stage of atomic and chemical complexity is reached that the phenomena, which we designate as vital, are observed. In the case of many inorganic and in some organic substances, we have good reason to believe that we know the interatomic relations and some of the laws that govern their changes. In the case of the more complex bodies, we have not yet reached this condition of knowledge, though we have so far found nothing to indicate that the atoms in bodies like protoplasm are not governed by laws differing rather in degree than in kind from those which control the atoms in less complex compounds.

In regard to the relation of electricity to vital processes and manifestations, there is dense obscurity in the lay mind, and in the minds of some scientific observers there seems to be a certain amount of misapprehension and unwarranted deduction. The average layman seems to believe that electricity and life are interchangeable terms, and

the better taught observer is apparently often under the impression that, because electrical influences have marked effect upon vital processes and many organic substances, there must be a close relationship between electrical force and what he considers to be by analogy the vital force. The deduction is false, and the inference that there is an entity which can be justly described as a vital force is unwarranted by any real evidence so far in our possession. We believe electricity to be a form of energy, and we may say that vital processes are manifestations of energy, but the two are not necessarily convertible, and the fact that a change in electrical state has apparently been demonstrated to occur in the course of certain vital manifestations, does not show that this electrical change is an essential part of the processes which are occurring, or that it plays any causative rôle whatever. The solution of the question and the promulgation of a satisfactory definition of life are matters of absorbing interest, but we are far from having enough facts at our command to begin to draw conclusions, and we must wait until the chemist and the physiologist have worked together much longer than they have up to the present before we can get an agreement among scientists as to what they mean when they talk about "life."

---

### Inebriate Women.

In these days when drinking is said to be greatly on the increase among women of all civilized nations, and in this country and in Great Britain among those of what are known as members of the upper circles, a discussion of inebriety as it affects the female sex may not be out of place. In the first instance, it would seem that the fact cannot be denied that there has been, among women of the smart set, both here and in Great Britain, a certain tendency toward the imbibing of stimulating beverages, but at the same time it is equally certain that the situation in this respect has been greatly exaggerated. The women of the lower classes in London and in some of the other large cities of the United Kingdom, have for long had the reputation of being somewhat addicted to drink. Whether, however, this failing has not been enlarged upon is a point which requires closer investigation before condemning them as a class.

Undoubtedly many of the articles which have widely pervaded the pages of journals and society papers in this country and in Great Britain have not been distinguished by a close regard for strict veracity. A well-known writer, in a London weekly journal a short time ago, drew a harrowing picture of the extent to which secret tippling is indulged in by ladies of the best society on the other side. He assured his readers that it was a common practice with women of rank to use their milliners and confectioners as a means of satisfying their vitiated tastes. As regards the milliners, they were induced by their customers to put down spirits and wines under the head of lace and so forth in the bills sent in to their husbands. That this picture is overdrawn is plain on the face of it. Nevertheless, those who have made it their business to discover the truth confidently assert that drinking has decidedly increased among women generally within recent times. The reason for these degenerated habits is, perhaps, not far to seek. Women in society, or in command of almost unlimited money, lead a life of continuous wear and tear; this after a time, and quickly with those who have inherited a neurotic temperament, brings on nervous exhaustion, which they endeavor to fight with alcohol or with drugs.

In the *Medical Times and Hospital Gazette* of August 1, 1903, the opinions expressed with regard to inebriate women by Dr. Braithwaite, the Inspector under the British Inebriate Acts is referred to. It has been regarded for so many years as an undoubted truth that women who have become confirmed drunkards are beyond all hope, that the statement has come to be looked upon as incontrovertible. At the present time this opinion by no means possesses the weight which it possessed once.

Dr. Braithwaite, who, of course, speaks with the authority of one who has had wide experience on the subject, is a dissenter from the old-time view, and says that, "as a matter of fact, women who give themselves a fair chance have at least an equal chance of good result," and he quotes instances. He thinks too that the popular impression does incalculable harm, for the woman who has given away to drink despairs of recovery, and her friends regard her with suspicion, although she has apparently reformed.

Women who have taken to the drink habit practice it in secret, as a rule, long ere the vice is discovered. When this occurs, they are pointed at by the hand of scorn, and becoming utterly careless of consequences, and losing all self-respect, brazenly pursue the downward path. It is this feeling on the part of a woman of position who is found to be addicted to the drink habit, and who thinking that she has thereby forfeited all claim to respect or esteem, that is probably an important factor in rendering her especially hard to treat successfully. As the *Medical Times and Hospital Gazette* remarks, "The matter is such an important one from the point of view of the common weal that it is to be hoped that other doctors, inspectors, and persons of similar experience will offer their testimony. Such a discussion would be welcomed, and could not be productive of anything but good."

---

### Stature of the Japanese.

The *Sei-I-Kwai Medical Journal* announces, in a recent issue, that Surgeon-Captain Nakamura of the Hiroshima Army Division has written an important paper on the question of the stature of the Japanese. The view has been expressed on more than one occasion, that the physique of the people has been keeping pace with their remarkable material, scientific, and literary progress. For several years Surgeon-Captain Nakamura has been collecting statistics bearing upon this point, and the result of his investigations go to show that these premises have been correct. The data collected cover the period of eleven years ending 1902, and appear to prove, in a convincing manner, that at any rate the Japanese as a race have increased in stature, steadily and systematically. Japan enforces conscription, and the number of men examined practically included all those who had reached the age at which they were liable for army service. Consequently the figures obtained were comprehensive and to be depended upon.

According to the *Sei-I-Kwai Medical Journal*, "The data given proves that the number of those who measure 5.4 shaku (5 feet 4½ inches) or above and 5.2 (5 feet $1\frac{7}{10}$ inches) to 5.4 shaku is steadily advancing, and that the number of those coming under the two shorter headings is gradually declining. In 1892, for instance, those who measured above 5.2 shaku numbered 42 out of every 100 examined, and the

corresponding number increased to 44 in 1902. On the other hand, the number of those whose height was below 5.2 shaku decreased from 58 to 52 during the same period. If in gaining in height the Japanese have not lost in muscle and weight, the showing should be most encouraging as a sign that the national physique is developing *pari passu* with the wonderful growth exhibited in other directions.

---

THE TREATMENT OF GOITER BY DISTILLED OR RAIN WATER.

In the *Lancet*, July 18, and again on July 25, were letters from two medical men describing the successful effect following the treatment of goiter by the use of distilled or rain water. In the first letter Dr. C. A. Rayne of London gave the history of three cases of goiter which in one instance yielded entirely to this remedial measure, and in the two others showed considerable amelioration. He claimed that giving the patient no drink but rain or distilled water was an entirely new method, and in this view he was upheld by Dr. F. Roberts of London, who also said he thought an important discovery had been made.

However, Dr. Louis E. Stevenson, writing to the *Lancet* of a later date, denied that the treatment was by any means new, but said that it had been familiar to physicians in diverse parts of the world for a long time. The writer further said that several cases of cure by this means had occurred in his own practice, and that he had pointed this out some years ago, at a meeting of the Border Branch of the British Medical Association.

Dr. Rayne had raised the question whether some other maladies to which we are become more liable, may not be related to some undiscovered influence in our water-supplies, which are more and more derived from reservoirs and collections through strata of an unknown nature. Dr. Stevenson, on the other hand, did not think that the cure depended on either rain or distilled water, but on the fact that the patient was drinking a fluid free from the goitrous poison, and in proof of this he quoted the following instance from the writings of St. Lager: "Kessler says that round Schemnitz in Hungary the goitrigenous action of the waters is so evident that those who go to drink the water of a neighboring valley have the satisfaction of seeing their tumors disappear."

Other instances of a like nature could be quoted. Among these another, also from St. Lager, in which it was shown by the evidence of military surgeons who had observed epidemics of goiter in many places, that the officers and non-commissioned officers who drank only wine escaped the disease. That rain water or distilled water, whatever be the cause, has a good effect on the course of the disease may be regarded as certain, and it would seem more than likely that the disease is due to some quality of the water consumed.

---

**Orrhotherapy in the Typhoid Fever of Children.**—Alberto Josias concludes from his experience in the treatment of fifty cases of typhoid fever: (1) That the average death rate caused by typhoid fever among children in the Parisian hospitals, where they are treated by cold bathing and drugs, averages 14.2 per cent. (2) The average death rate among children suffering from typhoid fever in the Bretonneau Hospital, where they are treated by anti-typhoid serum and cold bathing (72° F.), is 4 per cent. These statistics establish beyond doubt the value of the serum. Its discovery by M. Chantemesse is a distinct advance in scientific medicine.—*Medical Press and Circular.*

## News of the Week.

**A Plague Scare from Cuba.**—A few days ago a morning paper printed a long article on a mysterious and exceedingly fatal disease (possibly plague or yellow fever) which was said to have appeared at Daiquirí near Santiago de Cuba. According to the description given, the disease "attacks persons who have suffered from intermittent malaria fever; commences with very heavy chills, lasting from fifteen to twenty minutes; high fever 107°; severe pains in joints and anxiety at end of chills or before patient begins vomiting, which is almost impossible to control. About six hours from commencement of attack the patient assumes a yellow color, more or less pronounced, in proportion to the attack, this always, however, being more pronounced than in yellow fever. The breathing becomes labored, affecting all the thoracic and abdominal muscles. Hiccough is frequent. Patients not treated during first few hours of attack have not the slightest hope of recovery. Pulse is 160; respiration, 38 to 58. A microscopical examination of the blood shows the microorganism of malaria. Treatment: frequent doses of quinine." A copy of this report, made by the company physician, was sent by the officers of the steel company, among whose miners the affection was noted, to the pathologists of the Jefferson College Hospital and University Hospital of Philadelphia, and of the Medical Department of Columbia University in New York, and in the process found its way into print. It was the officers of the company, however, who wished to be enlightened as to the nature of the disease, and not the physician, who had already made the diagnosis of pernicious malaria. This diagnosis has been confirmed by Dr. Carlos Finlay, Chief Health Officer of Cuba, who denies the existence at Daiquirí or elsewhere in the island of either plague or yellow fever, the only cases of fever there being malarial, among which there are always likely to be pernicious or hæmoglobinuric forms. Indeed, three deaths from blackwater fever were reported from Daiquirí during July.

**Recrudescence of the Cattle Plague in Massachusetts.**—It is reported that four cases of foot-and-mouth disease were recently discovered in a herd of cattle at Wakefield, Mass. In consequence of this the Maine Board of Cattle Commissioners has reëstablished the quarantine against Massachusetts cattle.

**Fourth of July Tetanus.**—In the *Journal of the American Medical Association* of August 29 is a special article giving statistics of the deaths from tetanus secondary to wounds received in celebrating Independence Day after the inane method followed in most of the northern States. According to the figures compiled by the writer of this article there were 415 deaths from this cause. Most of the victims were boys, and most of the deaths resulted from blank cartridge explosions, causing wounds in the hands. Of the deaths 49 are credited to Illinois, while New York reports only 36. Pennsylvania leads the list with 82 deaths. Ohio had 67 deaths. The deaths in other of the States of the Middle West were as follows: Indiana, 11; Wisconsin, 11; Michigan, 29; Iowa, 14; Minnesota, 16, and Missouri, 29.

**Municipal Hospital, Philadelphia.**—Dr. W. M. Welch has been retired as physician in chief to become diagnostician and consulting physician, Dr. Jay F. Schamberg has resigned as assistant physician, and Dr. B. Franklin Royer has been made chief resident physician.

**The Medical Corps of the Turkish Army.**—Reports from Constantinople say that seven hundred medical and veterinary students have received their diplomas and commissions without having passed the usual examinations, and have been drafted into the Turkish army.

**Dr. Alfred Meyer** of New York City has been appointed chairman of a committee in charge of the Section on Sanatorium Treatment of Tuberculosis of the American Congress on Tuberculosis, to be held in Washington, D. C., April 4, 5, and 6, 1905. It is probable that the climatic and other methods of treatment will be comprised under the work of this committee.

**The Pasteur System Attacked.**—Dr. Duata, professor of hygiene at the University of Perugia in Italy, has published in a Milan newspaper a severe arraignment of the Pasteur treatment of rabies, which he says causes but does not cure the disease. Before the introduction of this mode of treatment, he says, the average annual number of cases of rabies in Italy was sixty-five, but since the institution of the Pasteur method the annual average has risen to eighty-five.

**Physicians Charged with Drug Pilfering.**—Three young physicians connected with the St. Louis Board of Health have been charged by the Health Commissioner with stealing drugs from the pharmacy of the city poor house, and warrants for their arrest for petit larceny have been issued.

**Edison's Cancer Cure.**—The latest cure for cancer is announced by Mr. Thomas A. Edison, the inventor. He has invented a new theory of the pathogenesis of cancer, which we are unable to grasp from the specifications published. But the cure is very simple; one has but to take a hypodermic syringeful of blood from a healthy subject and inject it into the body of the affected person in the region of the cancer. The trick is easy enough and its inventor gives it free to the world, for, although he has, it is said, taken out nearly 800 patents on his various inventions, he is safe in believing none would be granted him on this.

**North Dakota State Medical Society.**—At the recent annual meeting of this society the following officers were elected: *President*, Dr. W. H. Bodenstab of New Salem; *Vice-Presidents*, Drs. J. A. Rankine of Jamestown and Paul Sorkness of Fargo; *Secretary*, Dr. C. L. Brimi of Cooperstown; *Treasurer*, Dr. W. H. M. Phillip of Hope; *Delegate to the American Medical Association*, Dr. V. H. Stickney of Dickinson.

**The Restoration of the Army Canteen.**—In his annual report as Commander of the Department of Texas, Gen. Frederick D. Grant renews the argument for the restoration of the post exchange or canteen. The canteen, he says, is the enlisted soldier's clubroom, into which no vice or degradation can intrude. There the soldier is guaranteed certain privileges which, so long as not abused, prove a bulwark against the temptations and dangers that now surround almost every post in the army, and especially border posts. To close the doors of the soldier's garrison club and send him out into the haunts of iniquity and vice run by moral vultures is a wrong to the soldier as well as to the community in which the soldier is stationed.

**Christian Science as Dangerous for Animals as for Men.**—A Texan farmer recently brought suit against a railroad for fatally injuring his team of horses. The testimony was straight, and it seemed that the plaintiff would win his contention without doubt. He went on the stand in his own behalf, and what he said in answer to questions strengthened his case until the attorney for the railroad asked him what treatment he had given the horses. He answered that he had given them the Christian Science treatment only. He had prayed for them, but had put nothing on their wounds and had done nothing to relieve them. The jury thereupon decided that he had caused the death of his horses by neglect, and returned a verdict for the railroad company.

**Strike of Club Doctors in Germany.**—For some months there has been going on a controversy between the management of the German National Sick Insurance Funds and several thousands of physicians employed by the free hospitals, or in outdoor relief. About three months ago the physicians threatened to leave the State's service in a body unless their compensation was increased from 7½ cents a visit to at least 10 cents. They also demanded certain other ameliorations in their condition. The physicians in the Muhlhausen Hospital, under the leadership of Dr. Schloss, actually did go on strike for a time, but resumed their duties pending an investigation. Dr. Schloss died quite suddenly last week, and the police arrested Dr. Schwartz, superintendent of the Muhlhausen Hospital, on the charge of having killed his colleague in a duel. It was known that the two had had a violent quarrel and hence the suspicions of the authorities. The alleged surviving principal and the seconds apparently tried to conceal the cause of Dr. Schloss's death, attributing it to blood poisoning, according to one report, and to an operation according to another. The police took possession of the body as it was about to be cremated at Gotha, and the arrest of Dr. Schwartz followed. He was, however, released the following day, as the testimony plainly showed that the suspicions of the police had no foundation in fact.

**Dr. Augustus Pohlman**, for the last three years instructor in anatomy in the medical department at Cornell University, has resigned to accept an assistant professorship in anatomy in Johns Hopkins University.

**Lincoln Hospital to Be Enlarged.**—Plans have been filed with The Bronx Building Bureau for the enlargement and remodelling of the Lincoln Hospital at One Hundred and Forty-first street and Concord avenue, Bronx borough. An extension, 28 by 31 feet, is to be added, the improvements costing $15,000.

**A Money Lender's Legacy to Charities.**—Sam Lewis, the most famous and most fashionable usurer in England in the past generation, who died two years ago leaving a fortune of £2,500,000, bequeathed over £1,500,000 to charitable and other public uses, including £400,000 for dwellings for the poor in any part of England that the trustees may select, and £100,000 for the Jewish Hospital.

**Increased Health Board Estimate.**—Health Commissioner Lederle of New York City has sent to the Mayor's office his estimate of the expenses of the Health Department for 1904. He asks for a total appropriation of $1,631,500, an increase of $583,778 over the appropriation for the current year. Of the amount asked for $1,060,840 is for salaries. There is an increase of $20,000 in the salary list of the office employees, the increase being due to the necessity for a larger force of employees and to a proposed increase in salary of some of the present staff. Of the appropriation asked for, the sum of $570,660 is for miscellaneous funds. These funds are divided as follows: For the removal of night

soil, offal, and dead animals, $78,300; for sanitary police, $128,400; for supplies and contingencies, $45,760; for disinfection, $49,550; for hospital fund, $158,250; for support of ambulance service, $24,800; for laboratory fund, $30,600; for abatement of nuisances, $5,000, and for the construction and equipment of a new steamboat, $50,000.

**Yellow Fever in Mexico.**—Much concern is felt over the wide extent of the epidemic of yellow fever on the Gulf coast of Mexico. On Saturday last there were eighty-five yellow-fever patients at Merida. At Progreso there were nineteen patients, and the sanitary authorities fear the spread of the disease to other points in the Yucatan peninsula. The fever is epidemic in several towns between Tampico and Monterey, and at Linares and Victoria the daily death rate is very large. It is also spreading to towns situated some distance from the railroad. At Tampico the death rate has increased during the past few days despite the efforts of the Mexican health authorities to control the epidemic. Upon instructions from Austin, a quarantine has been established at El Paso, Texas, against Monterey, Victoria, and Linares.

**Drugs Cannot Be Sent by Mail to Sweden.**—Attention has been called to the fact that pharmaceutical preparations can be forwarded in the mails to Sweden only when sent to drug stores and certain scientists and manufacturers who have been granted official permission to receive them. All drugs which reach that country bearing other addresses are returned by the Swedish authorities.

**A Woman Dentist Starved to Death in the Klondike.**—The death from starvation of Mrs. Edith White, a dentist, is reported from Alaska. She was a graduate of the Dental Department of the Minnesota State University, and was a practising dentist in Dawson City for some years. She started from that place to go into the interior, and nothing more was heard of her until her body was found on the banks of Copper River. With the body was found a diary in which the starving woman had recorded her sufferings.

**A New Journal of Syphilography.**—Dr. T. Barthélemy, physician to Saint-Lazare in Paris and formerly chief of clinic at the Hospital Saint-Louis, has begun the publication of a monthly journal, *La Syphilis*, which will be devoted exclusively to the study of the disease designated by its title. The first number, dated July, 1903, contains an article on "Syphilis of the Stomach," by Prof. Alfred Fournier, an analytical review by Dr. Lévy-Bing of two articles on the same subject by Prof. Dienlafoy, and an article entitled "General Program of Syphilography" by the editor. There are also reports of clinics by Drs. Gaucher and Brocq, and an account by Dr. Barthélemy of an untreated case of lues. Following these are the usual abstracts from other journals, society reports, correspondence, therapeutic notes, and bibliography.

**A Tent Colony for Consumptives.**—Scranton, Pa., is making efforts to provide for its consumptive residents who cannot care for themselves. A free dispensary is conducted in the city, and a tent colony has just been started on West Mountain, not far away. The site comprises about thirty acres, fourteen hundred feet above sea level. About half of the tract is under cultivation; the other half is covered with an attractive forest. This is the undertaking of a private society, which is raising its funds by appealing to all the citizens of the place for contributions. The first patients were taken down early in August, and already an improvement is noticed. Tents have been provided for fifteen, but almost the same number of applicants have been refused. The plan is to erect permanent buildings in the fall. There is a report that another hospital also is contemplated.

**The Late Dr. Jannat Ernestine Hills.**—At a special meeting, held August 1, 1903, the medical staff of the Willard State Hospital unanimously adopted the following resolution:

"Dr. Hills had been a member of the staff since November 14, 1895, and had born her full share of the burden of work. To the patients she was ever a sympathetic, interested, and sturdy friend, as well as their faithful physician. She gave to them what was best in her personal and professional life, intermingling with the services required by her position those small kindnesses of word and deed which go so far in promoting happiness, and which are an unfailing indication of a benevolent heart. To her associates of the medical staff she was a warm-hearted, generous, encouraging loyal friend, and a helpful and willing colleague. Whatever she did was done heartily, and the claims of duty, charity, and friendship never appealed to her in vain. It is, Therefore,

"*Resolved*, That we hereby express our sincere sorrow that she has been taken away, and our heartfelt sympathy with her relatives in their sore affliction, and

"That a copy of this memorial be placed on the files of the hospital, a copy sent to her sisters and brothers, and a copy furnished for publication to the medical and lay press. For the medical staff,

"WM. AUSTIN MACY, M.D., Superintendent."

**Obituary Notes.**—Dr. R. HENDERSON GRAHAM of Washington, D. C., died there on August 24 of peritonitis, aged fifty-three years. Dr. Graham was a native of Ohio, but removed to Washington in 1889. He was a graduate of the Columbus, Ohio, Medical College in 1879.

Dr. JOHN M. EVANS, after whom the town of Evansville, Wis., was named, died there on August 23, aged eighty-three years. He was a graduate of the Indiana Medical College in the class of 1846. Dr. Evans was the first mayor of Evansville, and served in the legislature at different times. He also was prominent in Masonic circles.

Dr. ALEXANDER MONTAGUE ATHERTON, twenty-eight years old, died at Liberty, New York, August 28. He was born at Honolulu, and was graduated in arts from Wesleyan University at Middletown, Conn. Later he studied medicine and obtained his degree from Johns Hopkins University in 1901. He won a service in the City Hospital, Blackwell's Island, New York, where, during his interneship, his health began to fail. Dr. Atherton recently married Miss Eleanor Louise Baker of Providence, R. I., and leaves besides his widow, his mother, two sisters and two brothers, all of Honolulu.

Dr. GEORGE B. RUSSELL, one of the oldest and best-known physicians in Michigan, died at his home in Detroit, on August 31, aged eighty-seven years. He was born in Russellville, Chester County, Pa., and was graduated from the Jefferson Medical College in 1836. His first hard service was during the cholera epidemic in Philadelphia, in 1836, and again in the outbreaks which raged in that city in 1844 and 1845. He subsequently removed to Detroit.

Dr. WILLIAM E. ALLEN died at Scranton, Pa., on August 25. He was a veteran of the Civil War and for twelve years Health Officer of the city of Scranton. He was a graduate of the Albany Medical College, in the class of 1856.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

MORE ECHOES FROM SWANSEA—THE LATE DRS. PLAYFAIR, SWAYNE, BALFOUR, TATHAM—APOTHECARIES WHO ARE PHYSICIANS AND SURGEONS—SMALLPOX.

LONDON, August 14, 1903.

As friends turn up after their Swansea outing—a large proportion only staying in town a short time before their more definite holiday—we hear more about the meeting of the association, especially from a social point of view. The first impression from all reports was one of abounding Welsh hospitality, and this is confirmed in all directions. The amusements, too, were on a large scale, and though Swansea cannot boast of much beauty it is an excellent center from which to explore the splendid scenery of Wales, its own near surroundings offering considerable attractions.

Of course Welsh subjects were prominent. Welshmen who had achieved any sort of distinction came in for many attentions, and those who were otherwise unknown found a Welsh parentage or birthplace a passport to pleasant places. Dr. F. Roberts began his address in medicine by alluding to the fact that forty-five years ago the President, Dr. Griffiths, who had just introduced him, and he himself left their native land to begin their career together at University College, London. He could, he said, go back further, for he was apprenticed in Carmarthen, and so could speak of his jubilee in the profession.

This year's souvenir, presented by Messrs. Burroughs and Welcome, also happily partook of the genius loci. It was an elegant illustrated little book on "Antient Cymric Medicine." A president-elect in search of a subject might take a hint from this now that we are waking up to the subject of the history of medicine.

Another souvenir (presented by the mayor and corporation) was a noteworthy little book illustrating the docks, shipping, and manufactures of Swansea, as well as some of the most charming views in the neighborhood.

A novelty in accommodation was a camp for members who would like to try a tent life for a few days. Only thirteen members availed themselves of this, but they must have found it a most agreeable change from their ordinary mode of life. Each had a tent to himself and each was made an honorary member of the yacht club for the time. Here is another hint for future organizers.

The annual representative meeting should develop into an important part of the proceedings, but in the first year of this new departure it was hardly to be expected that anything striking would occur. Sir Victor Horsley was elected chairman, and in thanking the meeting declared this the "highest honor the profession—always most kind and generous to him—had conferred upon him." This strikes me as rather an exaggerated view of the value of this mark of confidence among medico-politicians. It was decided not to admit reporters for the local press to these meetings of representatives—a very sensible decision, considering the observations likely to be made anent medico-political and ethical matters.

I was pleased to hear that a protest was made against encumbering the journal with two supplements. For years the *excerpta minora* of other journals have been relegated to a supplement, and now medico-political stuff is to occupy another. The editor, however, seems to have satisfied the meeting that this plan was approved by the majority—so let the majority rule. But the journal is terribly heavy (unwieldy? or—or both?). For those who want to bind it I would suggest making up four volumes a year of it.

The ethical committee has been very busy for many months attending to other people's business, and naturally put in a full appearance at the meeting "to bring accusations of advertising," so it is said by some, but perhaps they or their friends were annoyed. It is rather a ticklish subject, and some of our ethical rabbis are apt to display *trop de zèle*.

"There are numerous 'antis' about," said Dr. Roberts toward the conclusion of his address, "but for downright impudence and insolence the antivivisectionists 'hold the field.'" This was, of course, very shocking to poor Stephen Coleridge who, wrote to the Swansea papers that it made "a claim on behalf of doctors to dictate to mankind on a question of ethics." His logic and his ethics seem on a par.

Dr. William S. Playfair died yesterday at St. Andrews, to which he traveled last month by easy stages from Florence, where he had an attack of apoplexy. Never very strong, his health had declined very much of late, and some months ago he went to Italy. He was born in 1836. His father, Dr. George Playfair was Inspector-General of Hospitals, Bengal, and William, when he grew up himself, and graduated M.D. (1856) entered the Bengal service and served in Oude through the mutiny. Afterward he officiated as professor of surgery in the Calcutta College. His health did not stand the climate, and he returned to England about 1863. He established himself as an obstetric physician in London, and became professor of midwifery at King's College, serving also on the staff of the hospital. He also held other appointments, including that of accoucheur to the Duchess of Saxe-Coburg-Gotha and the Duchess of Connaught. He was for some time examiner in his specialty at both the London and Cambridge Universities. His textbook has gone through nine editions here, and I do not know to what extent it has been reprinted on your side, but no doubt you are aware that it was for long a very favorite manual with both students and practitioners. You will also remember a painful incident in his otherwise successful career—the action brought against him in 1896 by a patient for breach of professional confidence. She was awarded heavy damages. A testimonial of confidence and sympathy was subsequently presented to him. The funeral takes place to-morrow at St. Andrews, where his two brothers, Lyon and Sir Lambert, are buried. Lyon was many years professor of chemistry at Edinburgh, but when the university was enfranchised abandoned science for politics, became postmaster-general and Lord Playfair.

Dr. J. G. Swayne of Bristol, whose "Obstetric Aphorisms" was a favorite book with several generations of students, died on the 1st instant, aged eighty-four. He was born in Bristol (1819) and educated at the college and Royal Infirmary there. He came to London then, and after a course of study at Guy's Hospital graduated at the London University, taking the M.B. in 1842 with two gold medals (medicine and midwifery). Three years later he proceeded to M.D. He became lecturer at the Bristol School and obstetric physician to the hospital, appointments he held for about half a century. He was also physician to the Children's Hospital and other Bristol institutions.

Another octogenarian physician of great reputation passed away on the 9th instant, viz., George William Balfour of Edinburgh, M.D., F.R.C.P.E., etc., whose name you will recognize as one of His Majesty's Physicians-in-Ordinary for Scotland. His death is to me a personal loss, though I had lately had but little direct communication with him. Past associations come to the memory with extra distinctness as they always seem to do when our friends are called away, and as life advances how often our seniors precede us. He was related to R. L. Stevenson, so you may suppose he was interested in literary questions and had a fund of information about them. But what is perhaps of more importance to your readers is the great position he so long held as an authority on diseases of the heart, though his profound acquaintance with the whole range of medicine made him one of the great clinical teachers in Edinburgh—so famed for its great teachers. He has left his mark in the Royal Infirmary, and successive generations of grateful and admiring students will cherish his memory.

Dr. John Tatham died on the 3d instant, aged sixty-nine years. He was consulting physician to Brompton Hospital for Consumption, where he had worked steadily for a number of years. He was M.D. of St. Andrews and F.R.C.P. He has been for some time an invalid.

An association of scientists of the Apothecaries' Society has been formed to press effectively their claims to a designation expressive of their qualification to practise medicine, surgery, and midwifery. They are at a disadvantage in this respect in comparison with the scientists of the conjoint board, who can flaunt the names of two royal colleges. But they must get an Act of Parliament to effect a change—no easy task—and while attempting it they are assuming something in calling themselves the "Association of Physicians and Surgeons of the Society of Apothecaries."

The epidemic of smallpox at Cambridge continues. Last week the total number of cases reached 130, and there were eight deaths. It is unfortunate that at first the outbreak was either denied or spoken of as chickenpox.

In a northern town the out-patients in the waiting room were told that one who had been among them was found to have smallpox, and all were offered vaccination. A panic ensued, and in the rush for the door one woman, unable to reach it, is said to have dropped her baby out of the window and jumped after it. No doubt a ground floor window. Some of the anti's think it was vaccination the patients were so afraid of.

A few fresh cases have occurred in the western suburbs of London, Ealing and Brentford, fifteen or sixteen altogether, generally mild.

## LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

DIFFICULTIES IN OBTAINING DISTILLED WATER—CONTAMINATION OF THE MANILA WATER SUPPLY—HEALTH CONDITIONS—PARADE OF BOARD OF HEALTH OFFICIALS—SANITARY DISTRICTING OF MANILA—QUARANTINE IN FORMER TIMES—PROSECUTION OF QUACKS—INSUFFICIENT PAY OF HEALTH OFFICERS—RECOGNITION OF THE MANILA MEDICAL SOCIETY BY THE AMERICAN MEDICAL ASSOCIATION.

MANILA, July 6, 1903.

An incident has lately occurred in Manila which shows how many cases of cholera and dysentery, occurring in persons who believed that they had taken every precaution against these diseases, may readily be explained. It seems that a prominent American Government official was taken down with dysentery and many of the clerks in his office also suffered from intestinal disorders, and suspicion fell upon the supply of "distilled" water furnished for drinking purposes at the office. The Filipinos whose duty it was to procure the water from the government distillery were interrogated, and they swore by all the saints that the water had been procured from the proper source. A sample was, however, sent to the government laboratories for examination and was found to be an unusually foul water, containing the amœba of dysentery. Confronted with this evidence of their faithlessness, the Filipinos then confessed that they had procured the drinking water from the most handy source of supply, in spite of the fact that but little more trouble was required to get the distilled water ordered. The average Filipino, who is perfectly willing himself to use the most filthy and obviously contaminated water for drinking and cooking purposes, commonly regards the Americans as somewhat crazy on this water question, and he humors the American in his "whim" for distilled water just so long as he is himself under the surveillance of some person with power to make him follow instructions in this respect. He does not understand why he should be forced to walk or ride any distance to procure water when there may be an abundant supply close at hand. He is absolutely untrustworthy in such matters, yet it is quite impossible to watch a servant or employee at all times, and many Americans, particularly those who have to live in the cheaper class of boarding-houses, are practically obliged to place their health and lives at his mercy. Even in the higher class of places, this holds true and the best and most expensive hotel in Manila was lately detected serving to its guests water advertised as being distilled but which had never been near the fire. The Filipinos, Chinese, and Spaniards all appear to stand about on the same level in respect to sanitary matters, and refuse or evade the performance of duties upon which the most elementary rules of health for these islands depend. Fortunately, the incident quoted has resulted in nothing more serious than putting the official and a large part of his subordinates into hospital for some days, and has drawn attention to the very great danger resulting from the placing of too much responsibility upon an indolent and perverse Malay. The papers have commented freely on the episode, and the American colony will probably be more careful in the immediate future. Apparently the only way to be absolutely safe is to get the water for one's self from the distilling plants, and the next best thing would be the institution of coupon tickets which could be punched only at the place where such water is distributed. The necessity for pure water has been so frequently and forcibly emphasized, by sickness and death from the use of water from an infected source, that the government distilleries have lately reduced the price of distilled water to two cents a gallon, and the newspapers are urging a still further reduction in cost. To those accustomed to the pure cold waters of the homeland, the absolute necessity for boiled water here is not at first apparent, but experience shows that all except the natives who use the surface waters of the Orient, without boiling, are absolutely certain to contract water-borne disease sooner or later—and usually sooner.

As a number of cases of cholera have lately appeared in several of the small towns located on the water shed from which the water supply of Manila is drawn, and as apparently the local authorities were both unwilling and unable to take the proper measures to suppress the disease and prevent the water supply of the city from becoming infected, the Board of Health has taken sanitary matters out of their hands and assumed absolute control. For the past fifteen months the country people have been kept away from the river by an armed guard, and they feel that their interests have not been considered in connection with the welfare of Manila. The Filipino is essentially an amphibious creature, and this deprivation of the use of the Mariquina river has been almost in the nature of a calamity to those living in the vicinity. They were allowed to contaminate the water to their heart's content in the good old Spanish days, and present restrictions are regarded as a direct infringement of their rights. As a result the people are hostile to sanitary control, break every sanitary regulation where it can be done with impunity, and have been certain of avoiding punishment at the hands of the native judges when detected in breaches of sanitary regulations. The Board of Health is fortunately now dealing directly with them with a firm hand. A medical inspector is in charge of the entire watershed, and is assisted by about forty American and Filipino sanitary inspectors. A disinfecting gang with outfit has been sent up from Manila, a company of native constabulary has been assigned to duty as sanitary police, and the river is quarantined and patrolled by a considerable force of American soldiers. As a result of these energetic measures, cholera is being rapidly stamped out and the city water supply has so far been kept free from infection by cholera. This water question in Manila will always be a most serious problem until the water is drawn from a source above contamination. The surveys to this end have already been completed and plans are being perfected as rapidly as possible. The engineer in charge states that he will be able to bring pure water into Manila within six months after beginning work, though the construction of the permanent dam will require about two years for its completion.

The reports issued by the Board of Health, including June 30, 1903, give the following information relative to past health conditions: During the entire cholera epidemic in Manila, since March 21, 1902, there have been 4,981 cases with 3,844 deaths; of these 313 cases and 288 deaths have occurred during the six months January 1 to June 30, giving a case mortality of 90.85 per cent. for the six months and 77.25 per cent. for the entire outbreak in Manila. Five-sixths of all the cases occurring in the last six months occurred during the month of May, when the Pasig river and canals became infected. Of the 39 cases occurring in the month of June, 38 proved fatal, a mortality of 97.43 per cent. The total cases from cholera throughout the islands since the outbreak of cholera are reported as 137,112, with 86,460 deaths. These figures are undoubtedly too small, as many cases and deaths have unquestionably never been entered on the official returns. The end of June finds the islands widely infected with cholera, but no serious epidemic prevailing at any point. A case now and then crops up in Manila, but the disease seems to be entirely under control in that city, and not liable to occur, except sporadically, if present success in preventing infection of the water supply is continued.

The outbreak of plague in Manila shows a total of 172 cases with 147 deaths during the six months, giving a mortality of 85.46 per cent. among the persons attacked. Hongkong has had nearly ten times as many cases during the same period, with a case mortality of over 90 per cent. Bombay has had, during the three months of January, February, and March alone, no less than 11,041 deaths from plague; and an annual death rate for these three months at the rate of 102 per thousand, which was largely due to plague. Only one case of plague has occurred in the Philippine provinces, in the person of a new arrival from Manila. Nearly all the cases in Manila have occurred in the Chinese districts and among Chinese. General inoculation of Chinese with antiplague prophylactic seems to have averted a serious epidemic.

There have been eighty-five cases of smallpox, with eleven deaths, occurring in Manila in the six months prior to June 30.

In the recent Fourth of July parade in Manila, the Board of Health made a fine showing, which received many compliments from the local press. The display included twenty-five vaccinators in their natty white uniforms, and forty sanitary inspectors in gray uniforms trimmed with green. There were eighty ratcatchers, in the white shirt, trousers and straw hat of the country, each carrying a rat-trap containing a live rat. These were followed by the corps of Pail Conservancy System men, one hundred strong, in white trousers, blue coats, and straw hats with red, white, and blue bands. Each man carried a large flag. There was a detachment of litter bearers of the ambulance service and several gangs of disinfectors, both in the same uniform as the sanitary inspectors. All these men marched like veterans, a fact explained by reason of a large proportion of them having at one time been insurrecto soldiers. The Board of Health display was concluded by decorated ambulances, disinfecting carts, and a float showing a Filipino house in which vacinators and inoculators against plague were at work.

All employees of the Board of Health are now attractively uniformed, a fact which adds much to their efficiency and pride in their work. The Filipino takes to a uniform like a duck to water; as it is not only a factor in personal adornment, but is an outward sign of the possession of dearly prized official authority which materially increases their importance among their own people. This racial love of power and display has been no small agent in attracting a good class of Filipinos to positions, under the government, for moderate pay, and the privilege of wearing a neat official uniform is more preferable to them than to occupy a better paid position without official status.

Manila has lately been re-divided into seven sanitary districts, each under a physician employed by the Board of Health. The sanitary work has been re-arranged and the force of employees re-organized, so as to reduce expenses without interfering with the efficient performance of duty. The sanitary machinery has been gradually developed by evolution during the existence of the Board of Health, and its work is now carried on in a most excellent manner. During the Spanish control, there was practically no sanitary organization except on paper.

While the Spaniards had enacted very drastic sanitary laws, these seem to have been enforced by the authorities largely for purposes of "graft" and corruption, and the sanitary deficiencies of persons with means could be conveniently overlooked if they were willing to pay for their immunity. As an instance in point, the story is told that with the appearance of plague in Hongkong and China, the Spaniards promptly authorized the detention in quarantine for twenty-one days of ships from infected points; when, in the opinion of the board of Spanish quarantine doctors at Mariveles, such quarantine was necessary. It is said that a certain English steamer arrived from Shanghai, with 600 coolies aboard, and was promptly ordered into twenty-one days' quarantine by the boarding officer. The ship's captain, however, quite understanding the situation, promptly requested that the medical board inspect his ship, and in the meantime sent around and collected some 3,500 pesos from the coolies and cabin passengers. When the medical board arrived, it was ushered into a cabin turned over to it for its "deliberations," upon the table of which stood the sack of silver. After some time the captain was informed that the ship was found in better condition than was anticipated and that only a delay of seven days' quarantine would be necessary. The captain, understanding from this that enough stuff had not been put up, thereupon urged the members of the board to remain with him for lunch, and in the meantime sent around and collected two pesos more from each passenger, or some 1,500 in all, making a total of about 5,000 Spanish dollars. This additional money was taken to the captain's cabin and put on the end of the lunch table, and when lunch was announced the captain requested the board to proceed and he would join them shortly. When he finally appeared, the board informed him that upon further consideration it appeared that the ship might safely proceed to Manila without more delay. With the large trade of Manila practically under their control, it was no wonder that the estimable medical gentlemen of the Spanish quarantine service were soon able to retire on a competency. The only people who could bring an effective complaint against such misuse of quarantine, namely, the steamship companies, did not choose to do so, as it would have involved them in difficulties with the Spanish authorities, who had it practically in their power to ruin the business of any company. Besides, this misuse of quarantine was really much to their financial advantage, as they could advertise that their ships were recognized as being so sanitary as not to be delayed by quarantine at Manila, and passengers and freight would be landed without delay or loss by deterioration. For this reason they asked and received higher rates for passenger and freight transportation, and when Manila was reached it was the passengers who were each assessed a small sum to pay the necessary blackmail, the shipowners bearing no part of such expense. The passengers themselves were glad to pay and thus avoid the tedious detention in quarantine which would otherwise have resulted—and everything was satisfactory except as regards the public welfare which, in Spanish times, did not count where money was to be gained.

The Board of Health has lately engaged in the prosecution of quack doctors under the provisions of the new medical practice act. One native "practicante" is in prison waiting trial for having caused the death of a child by an overdose of morphine, and an American ex-cavalry soldier has been convicted and fined for engaging in practice as a physician. So far the Board of Health has rather held its hand against the Chinese quack doctors, of whom there are many here, as the Chinese population still places much confidence in their own physicians and drugs, and the time is as yet scarcely opportune to take action against these men. With the exception of one educated Chinese physician who is a graduate of a reputable school, the others are ignorant impostors who pretend to diagnose disease by feeling the pulse or inspecting a sample of the urine. Besides the racial distrust of the Chinese for anything outside their own civilization, the fact that these quacks expect only a small fee appeals to their sense of economy. It is etiquette among all the Chinese doctors never to ask a fee or send a bill, but the patient or his relatives hand the doctor a sum of money wrapped in a piece of red paper at the conclusion of his visit. Usually this sum is only one or two pesos, for while the Chinaman is willing to pay liberally for anything else he wants, he seems to hold the services of his doctor as being of small financial value. Such a thing as a Chinese physician daring to set a valuation on his own services is unheard of, and would immediately lose him his practice, so that he is unable, like the American physician, to charge a rich patient enough to recompense him for gratuitous service rendered the indigent. If the Chinaman calls in a foreign physician he expects to pay a good-sized bill, but he denies this right of charge to physicians of his own race and would stand aghast if such a native physician should enter his shop, select some tea or silk, put his own valuation on it, and tender the shopkeeper its appraised value in pesos wrapped in red paper as he left the store. While physicians all over the world seem to have a hard time in making a living, the lot of the Chinese doctor seems to be doubly unhappy in this respect.

The Board of Health has lately lost a number of its best physicians, formerly medical officers of volunteers. These men were given their army pay and allowances after their discharge from the military service, but this arrangement continued not only until the end of the fiscal year. As under the new schedule of pay their pay was to be considerably reduced, a number of them chose to return to the United States. Four of these ex-volunteers are still continued at $2,500 per annum, while the civil-service physicians receive but $2,000. Obviously this rate of pay is not sufficient to attract and retain the best class of men. While a physician can support a family comfortably on such a sum in the provinces, in Manila it would represent merely a bare existence devoid of the little luxuries that make life tolerable in the tropics. In Manila, also, there is practically no opportunity for those in Government service to engage in outside practice.

Major Geo. H. Torney, the surgeon in charge of the large military hospital in Manila, is seriously ill with amœbic dysentery and will be returned to the United States for treatment on the next transport. He will be relieved by Major J. M. Banister, lately stationed at West Point, who is one of the most skilful operating surgeons in the army. A very large amount of operative surgery is done at this hospital, as its 350 beds are filled all the time with selected cases sent in for operation and treatment.

The Manila Medical Society has lately received notice of recognition by the American Medical Association, and admission to membership therein on the same basis as that of the medical societies of other States or territories, provided that its organization be extended to cover the island of Luzon and such other portion of the Philippines as may organize medical societies. This will necessitate a reorganization of the society on broader lines and will add much to its strength and importance. The society has at present some forty members on its list, and can readily secure a working membership of several times that number. At the last meeting the constitution and by-laws were so amended as to permit the publication of a journal named *Philippine Medicine*, to be the organ of the society, the establishment of which is now being projected.

---

**Operation for Prolapsed Rectum by Extraperitoneal Fixation of the Intestine.**—J. Rotter has modified Eiselsberg's operation of colopexy so that the intestine is made fast to the abdominal wall devoid of the parietal layer of the peritoneum. In this case the adhesions which form and hold the intestine in place are much firmer than those resulting from Eiselsberg's method, in which the intestine is fastened to the parietal layer of the peritoneum. The results are hence much more permanent than those which have been obtained by the latter method. The only variation in technique consists in dividing the parietal peritoneum in the proper location and suturing the gut to the abdominal wall through the incision thus made. The cut edges of the peritoneum are then united to the intestinal wall. Two cases are cited in illustration of the great advantages of this method. — *Deutsche medicinische Wochenschrift.*

**Treatment of Degenerative Diseases of the Nervous System by Massive Doses of Strychnine.**—Graeme M. Hammond says he was led to make a trial of this remedy in the class of cases mentioned by observing the good effects sometimes obtained by the same drug in large doses in the treatment of tic douloureux. The paper is based on the results obtained in the treatment of four cases of tabes, three of optic nerve atrophy, three of progressive muscular atrophy, and one case of pseudomuscular hypertrophy. These cases are reported in more or less detail. The writer's practice was to begin treatment with a very moderate dose, usually the $\frac{1}{60}$ or $\frac{1}{50}$ of a grain three times a day, and to increase the daily dose by about the $\frac{1}{100}$ of a grain. Sometimes in the beginning he increased the dose by the daily addition of $\frac{1}{100}$ of a grain but always diminished this to the $\frac{1}{100}$ of a grain after doses of $\frac{1}{4}$ grain were reached. In some cases he gave the medication hypodermically once a day, but could not perceive that the method possessed any advantages over giving it by the mouth three times a day. The maximum dosage varied according to the severity of the disease, from $\frac{1}{4}$ of a grain to $\frac{1}{2}$ of a grain three times a day. The results varied in the different cases. In none was there a restoration to the normal condition, that is to say a cure, and in none was that result expected, since neurons once destroyed cannot be recreated. In tabes the results were uniformly favorable, the ataxia being markedly reduced and the pain and other distressing symptoms being greatly reduced. In the three cases of optic nerve atrophy the degenerative process appeared to be arrested or retarded, but there was little actual improvement. In two of the cases of progressive muscular atrophy the morbid process ceased to advance, but in one case the course of the disease was not influenced in the slightest degree. In the case of pseudomuscular hypertrophy considerable improvement was noted in the muscular development and the rapid degeneration of the muscular system was arrested.

*Journal of the American Medical Association, Aug.* 29, 1903.

**Dangers of Striving for Interval Operations in Appendicitis.**—Richard H. Gibbons is of the opinion that the signs and symptoms of appendicitis are definite, and that the diagnosis should be prompt and the treatment should be surgical. He says that the primary danger is that the pre-inflammatory stage of the disease will not be detected, but the greatest danger of all in connection with the expectant treatment is that so many and serious complications arise to embarass the surgeon who operates late in the disease. Still another danger is that the patient who has survived the attack is loath to believe himself in danger, and consequently refuses surgical aid. These considerations lead the author to the conclusion that "immediate surgical intervention should be the shibboleth of every physician and surgeon."

**The Passing of Chronic Rheumatism.**—James J. Walsh, under this caption, discusses the necessity of transferring a number of painful affections from the column of chronic rheumatism, where, as he says, "they are all jumbled together to the manifest opprobrium of therapeutics, to separate columns, with regard to some of which we know our therapeutic impotency, but with regard to most of which we are fully aware that massage, rest, local treatment, and improvement of the constitutional condition will do much to get rid of the symptoms." He has collected no less than fourteen conditions, characterized by aches and pains, which are often called chronic rheumatism, but, in his opinion, without good reason. The most common form of pseudorheumatism is that painful condition resulting from flat-foot; another very common form of vague pain occurs in connection with occupation neuroses, and a third source of such pains is neuritis. Gout is now known to be much more frequent in this country than was formerly supposed, being seen especially in those who are subject to the influence of lead and who indulge too freely in malt liquors. A certain number of cases of so-called chronic rheumatism are really gouty in their nature. Again, rheumatoid arthritis, or arthritis deformans, occurs in three forms, some of which bear a very strong resemblance to rheumatism. It is, however, a disease by itself, usually following some infectious fever, such as influenza, parotitis, or tonsillitis. While admitting that there are probably a few cases of true chronic rheumatism, the author says these are so rare that he has never seen one, and he is inclined to believe that even the majority of these cases are the result of mixed infection.

*The Medical News, August* 29, 1903.

**Observations on Eighteen Abdominal Sections.**—Edward N. Liell reviews eighteen cases of abdominal section performed by him during the past year for various conditions existing within the abdominal and pelvic cavity. These were as follows: Five for ovarian cyst; five for cystic disease of ovary; four for appendicitis; one for intestinal obstruction; one for ruptured tubal pregnancy; two myomectomies for uterine fibroid. In one of the operations for cystic disease of the ovary, a cystoma weighing seventy-two pounds was removed successfully. The author says that it has been his good fortune, in his abdominal work for many years past, never to have met with an instance of secondary hemorrhage. He has never used anything but silk as a ligature, the size of the silk used depending upon the size and thickness of the pedicle; and he always sees to it that his ligatures are both well-placed and reinforced. Catgut he looks upon as treacherous, the main difficulty being in tying it firmly, so that it shall not slip, and another disadvantage being its liability to fray. The best means of prevention of abdominal or ventral hernia are small incisions and accurate coaptation of the various layers of tissue, thus securing firm apposition. In layer or tier suturing, desirable in patients with considerable adipose tissue, catgut and kangaroo tendon, in the writer's opinion, is preferable and meets the indications best, being absorbable.

**The Effect of Erysipelas upon Atrophic Rhinitis.**—Lewis S. Somers says that the favorable or even curative action of an intercurrent attack of erysipelas upon various morbid states has often been observed and recorded, but the effect of erysipelas upon atrophic rhinitis has very rarely been referred to, a careful search of the literature revealing but two cases, both reported by a single observer—Francesco. The first was that of a young girl, with ozena of seven years' duration, which had resisted all treatment. Erysipelas incidentally developed, originating at a point near the nostril and involved the face. After the attack had subsided, the odor and crusts entirely disappeared, the mucosa recovered its normal appearance, and as three years later there had been no relapse, the case undoubtedly could be considered as a complete cure. The second case was that of a young woman with ozena of the left nostril, which had resisted treatment. While nursing a brother with erysipelas of the leg, she developed the disease on the lobule of the left ear, and with the experience gained by the previous case, the author scarified the cheek near the ala nasi in order that the nasal chambers should become involved. The erysipelatous process then affected the entire cheek and nasal chambers, and when the patient recovered there remained no trace of the ozena. The writer's own case was in a man thirty-eight years old. His chief complaint was of an intensely fetid odor from the nose and the formation of thick, greenish crusts in the nasal cavities. Objectively the case presented the usual picture of atrophic rhinitis, without involvement of the sinuses. The nasopharynx was covered with partially dry and offensive mucous, and the pharynx was red, dry, and sclerotic. Various remedies tried by the writer and others had failed to give relief. One day the patient received a slight blow over the right eye, barely breaking the skin, and within twenty-four hours erysipelas appeared at the seat of injury and spread rapidly over the entire face and neck, and involving also the mucous membrane of the nasal chambers. The attack ran the usual course, and the patient was well again in about two weeks. An examination of the upper respiratory tract was made a few days later, and it was found that the ozena had entirely disappeared, the nasal mucosa was in part covered with but few crusts and easily removed, while the necessity for the frequent removal of the inspissated secretions had entirely disappeared. The nasopharynx and pharynx were still in part crusted and dry, but in no degree comparable to their former condition. No treatment was advised except occasional cleansing with an alkaline solution, as it was desired, in view of the favorable results produced by the erysipelas, to observe if the changes were permanent in character. At the present time, more than a year after the attack of erysipelas, the nasal mucosa remains somewhat shrunken and atrophic in patches over the turbinals, but is elsewhere apparently normal and the healthy areas are increasing in size; the secretions are practically normal and the occasional crusting produces no obstruction and no offensive odor. The upper pharynx is no longer dry, fissured, and covered with adherent secretions; the submucous tissue remains atrophied, but the epithelium has been fairly well restored.

*New York Medical Journal, August* 29, 1903.

**General Remarks on Diseases of the Stomach.**—Harry Warren Lincoln makes some apt and very practical observations under this head. He calls attention to the abuses, not to say the dangers, that may arise from allowing any patient to perform gastric lavage upon him-

self, and expresses the opinion that there has been altogether too much indiscriminate lavage of the stomach in recent years, and that the majority of patients will do well without local treatment. He disclaims any intention of underestimating the value of modern scientific examination of the stomach contents, but desires to make the enthusiast in this field pause long enough to see the wisdom of giving due consideration to the patient's general physical and mental condition. In this connection the potency of the neurotic element is emphasized, and the physician is advised to put the patient on a full diet, given in small quantities at short intervals, except in cases of ulcer or cancer, or when gastric motility is impaired.

**An Improvement in Radiography; a Print Obtained in a Few Minutes without a Dark Room.**—Sinclair Tousey makes use of a sensitized paper, which is sold in packages of a dozen sheets, and says it can be transferred to a light-proof envelope in any comparatively dark place. The prints can be produced in manifold by placing several sheets of the paper, one on top of the other, in the same envelope. After exposure of, say, two or three minutes, the sheets are removed from the envelope in a comparatively dark place, and are quickly dropped into the developing solution, where they are developed in about half a minute. After washing in plain water they may be used as proofs for immediate guidance in treatment, or the prints may be made permanent by immersion in the usual fixing solution, and then washing in running water for half an hour. In these prints the background is dark, the bones white and the flesh slightly shaded. The novelty of the method consists in the directness and rapidity of the process by which this result is secured

**Treatment of Toy Pistol Wounds.**—W. Scott Schley reviews the work done in this field at St. Luke's Hospital, and lays great stress on the extraordinary burrowing that takes place along connective tissue planes when the muzzle of the pistol is very close to the skin. The obvious corollary is that the wound should be thoroughly explored, and it is this truth which it is the special object of the paper to inculcate. A very free longitudinal incision is made into the skin, even when the wound appears to be insignificant, and by careful sponging and retraction the blackened tissue and powder grains are explored to their farthest limits. When this work is thoroughly done, the sloughy areas and extraneous matters curetted gently away, the parts freely irrigated with an antiseptic solution, the wound lightly packed with iodoform gauze and a wet dressing applied, healing is most rapid and satisfactory. Experience shows that, as a rule, there are two wads. For fresh wounds the exploration can often be made under cocaine, but in other cases a general anæsthetic should be employed. None of the cases treated in the past four years has developed tetanus, despite the fact that tetanus antitoxin has been used only four times; nevertheless the use of the antitoxin is thought to be a wise adjuvant.

*American Medicine, August* 29, 1903.

**Destruction of Bacteria in Vaccine Pulp with Potassium Cyanide.**—Harvey R. Gaylord and David E. Wheeler write that the work of Loeb on the fertilization of sea-urchins' eggs, in which he employed solutions of potassium cyanide, to prevent disintegration, and the work of Gorham, which appears to indicate that the diminution of the bacteria in the sea-water, as the result of exposure to the action of the potassium cyanide, was the essential factor in these experiments, suggested the possibility of employing this agent as a differential germicide in vaccinia. The fact that the delicate protoplasm of the sea-urchin's eggs could withstand the action of a solution as shown by Loeb, and still develop into swimming larvæ, suggested the possibility that the essential factor of vaccine, which they held to be a protozoon, might likewise be unaffected when thus treated. They obtained fresh vaccine, and after allowing it to become contaminated with organisms, in many cases to a state of putrefaction, treated it with varying strengths of potassium cyanide, beginning with $\frac{n}{1000}$ and extending to $\frac{n}{100}$. Portions of the fresh vaccine were introduced in into test tubes containing solutions of potassium cyanide of determined strength. In each case a control with salt solution was made, and at the end of three days to forty-five days the control and the cyanide solution containing the vaccine were plated out in the usual way. Children were vaccinated with the pulp so treated, with a result of thirteen takes out of eighteen vaccinations. The bacterioscopical examination showed that the solution of $\frac{n}{100}$ potassium cyanide exerted a complete bactericidal action upon the vaccine without in the least impairing its efficacy. The cyanide evaporates in a short time, and all traces of it can be removed immediately by placing the solution in a vacuum pan at 36° C.

**Enteroptosis.**—Thomas R. Brown concludes in this number an extended review of the various opinions held in regard to enteroptosis—its etiology, symptomatology, prophylaxis, and treatment. As a result of his studies, he has come to the belief that in the great majority of cases there is an underlying cause to be found in a characteristic body form—that is, there is a congenital weakness or fragility of tissues which predisposes to this condition, and also that in many cases, probably the majority, various accessory factors tend to bring about a marked displacement of the abdominal organs in those so predisposed. Of these factors most act either by increasing the pressure from above upon the abdominal viscera, as by the use of corsets, belts, etc., or by decreasing the pressure from below upward, as after severe illnesses, pregnancy, marked loss of weight and strength, etc., while in only a comparatively small proportion of the cases does injury or violent trauma form a part. As to the symptomatology, the tendency, he says, has been to ascribe far too many symptoms to the displacement of certain organs, notably the kidneys and the liver, and far too few symptoms to other viscera, especially the stomach and intestines. As to the treatment, far too much reliance has been placed by some on surgical interference. We should recognize that we are treating in the great majority of cases a displacement of several of the abdominal viscera, and surgical interference is justifiable only when the symptoms are referable to an especial displaced organ, or when dietetic, medicinal, and mechanical treatment have been tried without success. Thus the general practitioner and pediatrist should recognize the frequency of this condition, and should attempt by all means at their command to minimize its evil manifestations in those congenitally predisposed to this condition. The surgeon should realize that the condition is in the majority of cases a medical, not a surgical, disorder, and that the stitching up of the kidney is a most irrational means of treating general displacement of the abdominal viscera, and that he is frequently operating upon the kidney because of symptoms which are entirely referable to the displacement of the stomach and intestines. The gynecologist should realize that in many cases a retroflexed uterus is but part of a general enteroptosis, and it is as irrational to expect a relief of symptoms by the suspension of this organ as by the suspension of the kidney.

*The Lancet, August* 22, 1903.

**Sciatica.**—William Bruce discusses the nature and treatment of sciatica after a study of 418 cases, of which he had kept records, and an experience with as many more unrecorded cases. He finds the disease more common in males, and between fifty and seventy years of age. In examining these cases the patient should lie down on his back while the examiner tests all of the motions of the hip-joint and notes whether any of these cause pain. In almost every case of sciatica there is a wasting or flattening of the hip muscles, or an obliteration of the gluteal folds on the affected side. Frequently pressure with the end of the thumb reveals some point of tenderness over the capsule of the hip-joint. In the great majority of cases there is some lameness. After studying the nerve distribution of the region and Hilton's well-known views on the origin of pain, the author expresses the conviction that sciatica is not a neuritis of the sciatic nerve, but an affection of the hip-joint connected with the gouty or rheumatic diathesis, and that it merges into rheumatoid arthritis of the hip. In 52 per cent. of his own cases there was evidence of gout or rheumatism in other joints, and in 22 per cent. of lumbago. The vast majority of cases recover in time. The treatment of the acute stage may be summed up in the word "rest," but after the inflammatory period has passed massage and electricity are of the greatest service.

**The So-called Stokes-Adams Disease.**—William Osler says that this clinical condition, which is, in reality, not a disease but a syndrome or symptom complex, is characterized (1) by a profound disturbance in the automatic mechanism of the heart, producing a slowing of the pulse; (2) nervous symptoms, such as vertigo, syncope, pseudo-apoplexy and epileptiform attacks, and (3) secondary symptoms, such as Cheyne-Stokes respiration, cardiac asthma, and angina pectoris. He reports twelve cases, all males, and divides them into three categories, viz., (1) a group of severe cases; (2) a senile group, and (3) a group of milder cases occurring in younger men. The severer cases occur, as a rule, in the presenile stage, and present well-marked cardiovascular lesions. The senile cases are probably more common than is generally supposed, particularly in the form associated with vertigo. In the only necropsy of the series the arteries were found to be sclerotic, the root of the aorta and the coronary arteries were calcified, and the left ventricle was hypertrophied. In the majority of cases the valves are normal and the heart is not enlarged. The syncopal attacks

may be explained by transient interference with the blood supply to the nerve centers. In all cases the prognosis is bad, though in a few instances young persons have recovered, and quite commonly the condition lasts for many years. Sudden death is the most common termination. Very little can be done in the way of treatment. Iodide of potassium may influence the sclerosis, and the nitrites are indicated if there is high tension. A quiet, well-regulated life seems to be of the most importance; the treatment of the attacks consists in meeting the indications as they arise.

**The Significance of Pain and Tenderness in Inflammation of the Appendix.**—C. W. Mansell Moullin recalls the the well-known fact that the abdominal viscera are, for the most part, insensitive to pain, and points out that slight irritation of the parietal peritoneum causes acute pain. The least tension upon the root of the mesentery produces a pain referred to the umbilicus. The wall of of the bowel, whether inflamed or not, is quite insensitive. The author draws the following conclusions with regard to acute inflammation of the appendix: (1) Absence of pain is no indication that most serious mischief is not going on. (2) The initial pain of acute appendicitis, which is commonly referred to the umbilicus, is due to the peristalic action of the cæcum or of the appendix dragging upon the attachment of the peritoneum to the abdominal wall. (3) The cessation of this umbilical pain without improvement in the other symptoms is due to cessation of the peristalsis caused by the inflammation having spread to the muscular coat of the bowel. (4) The development of local pain means that the inflammation has spread from the appendix to the parietal peritoneum or to the post-peritoneal cellular tissue. (5) The presence of deep tenderness indicates that the inflammation has spread to the parietal peritoneum or to the cellular tissue beneath it. (6) Exceptionally the most tender spot lies at the back immediately over the crest of the ilium, and it is then strongly suggestive of an appendix lying behind the colon, or at least of inflammation spreading directly upward in that direction. (7) Absence of deep tenderness, when other well-marked symptoms of appendicitis are present, is of very grave import, because it usually signifies an overwhelming of the nervous system. (8) There is usually cutaneous hyperæsthesia, and when it is associated with other signs of inflammation of the appendix, the indication is clear that the wall of the appendix is involved. (9) Sudden cessation of this hyperæsthesia without corresponding improvement in the general symptoms suggests very strongly gangrene of the appendix.

*The British Medical Journal, August* 22, 1903.

**Hemorrhage into the Bursa Patellæ.**—J. B. Christopherson reports the case of an Egyptian soldier in Khartoum who fell from a horizontal bar striking his knee on a stone. Ten weeks after he was sent up to Cairo, and then his left knee was swollen and semiflexed, and presented the signs of a chronic synovitis of the joint without much effusion. There was no fluctuation anywhere, but there were two irregular thick transverse ridges across the patella suggesting callus thrown out after a fracture, but they extended beyond the lateral limits of the patella; the patella also seemed much broader than its fellow. The author thought it must be a case of tuberculous disease of the knee-joint, from its chronicity, appearance, and from its dating from an injury. As no improvement followed immobilization, strapping, etc., an incision was made vertically over the patella, and disclosed the bursa over the periosteum thickened to the extent of one-quarter inch and extending laterally beyond the patella. On incision this was found filled with an old extravasation of blood adherent and more or less organized in the angle between the anterior and posterior walls of the bursa. Toward the center the organization was less advanced, and in the middle a small cavity containing old blood. The patella was healthy, and the same size as that of the opposite leg. The bursa was dissected out and the wound was closed. A small quantity of fluid withdrawn from the joint was clear, and there was no evidence of tuberculous disease anywhere about the joint. The wound healed by primary union.

*Münchener medicinische Wochenschrift, August* 11, 1903.

**Diagnosis of Abscess of the Liver Following Dysentery.**—Schlayer says that the total leucocyte is of great value here. Abscess of the liver regularly shows a total hyperleucocytosis varying from 18,000 to 30,000, while other conditions liable to be confounded therewith give either a normal total count or a leucopenia. In the diagnosis between a hepatitis and liver abscess the situation is a trifle more complicated, as a few cases of hepatitis give total counts between 15,000 and 20,000. The point of differentiation is that here the high counts are not maintained, being more or less periodical, while in abscess the high figures remain constant. Many cases are here recorded as examples of the above principles.

**Banti's Disease.**—Fichtner reviews the literature and reports a case which he regards as typical in its main features although the etiology was peculiar. The patient was a man, thirty-two years of age, and had always been in good health until the beginning of his present illness, which dated from an abdominal injury received seven years ago. Following this accident the spleen began gradually to enlarge. In the fourth year of the illness there occurred an attack of biliary colic and the evacuation of a large number of gallstones. In the fifth year a purulent otitis media appeared which has never healed and soon thereafter an abundant ascites developed. The amount of fluid has varied from time to time, occasionally having entirely disappeared. The blood condition, so far as known, has been one of leucopenia combined with a variable grade of anæmia.

**Widal Reaction in Jaundice.**—F. Köhler reports a number of cases of jaundice in which a positive Widal was obtained in from $\frac{1}{5}$ to $\frac{1}{5}$ dilution. Similar cases have been reported by various observers. The cause of the agglutination in these cases is probably varied. In certain instances it is to be regarded as due to the presence of taurocholic acid and hence included in category of "agglutination due to chemical substance," but laboratory experimentation shows this cannot be always the case, since in many instances typhoid bacilli fail to agglutinate with taurocholic acid in solution. In those cases of jaundice due to infection with the colon bacillus it is probable that the reaction is to be regarded as a "class" agglutination due to the colon infection. When we consider the Widal reaction, we now know that it may be positive in five classes of cases, as follows: (1) typhoid fever; (2) liver diseases with jaundice; (3) due to chemical substances; (4) infection with the colon bacillus; (5) in other bacterial infections, such as those produced by the pneumococcus or meningococcus. All these facts deserve serious consideration in estimating the value of this reaction in the diagnosis of typhoid fever.

*Berliner klinische Wochenschrift, August* 10, 1903.

**Thyroid Preparation in Endemic Cretinism.**—Adolf Magnus-Levy after treating seven cases very satisfactorily with thyroid gland preparations comes to the conclusion that this is the proper treatment and that in no important respect does the endemic differ from the sporadic form of the disease. Although this is in contradiction to the prevailing belief, it is nevertheless supported by the therapeutic results in these cases when taken in conjunction with the clinical history of these two varieties of cretinism, since no cardinal differences are to be found in either the osseous, cutaneous, or mental conditions.

**Neutrophilic Granulations of the Leucocytes.**—Max Mosse says that myelocytes are the only leucocytes which possess genuine neutrophilic granules. This is so because when a blood smear which contains all the various leucocytes is stained with eosin-methylene blue solution of all the granulations of the leucocytes, only those of the myelocytes take the neutral tint—that is, a violet color. Those of the so-called polymorphonuclear neutrophilic leucocytes take a tint which is between that of eosin and methylene blue. They can only therefore be neutrophilic provided the eosin-methylene blue solution used in staining them is composed of two molecules of eosin and one molecule of methylene blue. Analysis of eosin-methylene blue solution, however, shows that this is not the case, and that such a solution is composed of one molecule each of eosin and methylene blue. Hence these leucocytes possessing a greater affinity for eosin than for methylene blue should be designated as "neutroacidophilic."

*Deutsche medicinische Wochenschrift, August* 6, 1903.

**Susceptibility of Domestic Animals to Tsetse Fly Disease (Nagana).**—Erich Martini inoculated a zebra with 1 c.c. of the blood of a horse suffering from tsetse fly disease, with the result that five months thereafter the zebra died under the fully developed clinical picture of this disease. The parasites were repeatedly obtained from the blood, being first isolated therefrom on the fourteenth day following the inoculation. So far as is known this is the first positive result which has been obtained in the zebra and it has generally been supposed that this animal was immune to the disease. Practical experience has very largely brought about this idea, since it is well known that under natural conditions zebras fail to contract the disease when they have apparently been exposed to infection. In most cases, however, the exposure of the animals has been of short duration—merely during transport—and in face of the above positive experiment it will be necessary to subject these animals to continued exposure before the question of their immunity or susceptibility can be definitely decided.

# Book Reviews.

DIE GALLENSTEINKRANKHEIT, ihre Häufigkeit, ihre Enstehung, Verhütung und Heilung durch innere Behandlung. Von Dr. WALTHER NIC. CLEMM. Darmstadt. Berlin: Georg Klemm, 1903.

THIS brochure of ninety pages, which is written in popular vein, is a diatribe against the operative treatment of gallstone disease. A plan of home treatment intended to replace a course at Karlsbad is given in detail, but loses in value through the recommendation of several proprietary preparations.

SURGICAL ASEPSIS. Especially Adapted to Operation in the Home of the Patient. By HENRY B. PALMER, M.D., Consulting Surgeon to the Central Maine General Hospital. With ninety Illustrations. Philadelphia: F. A. Davis Company, 1903.

THIS is intended to popularize, as it were, the practice of aseptic technique among those hitherto unhabituated to its use. The little volume is well written, and contains, in brief form, the essentials of the subject, together with practical directions for the carrying out of the principles involved. Lists and illustrations of the instruments required in the commoner operations are given, and in many ways the book will be a convenience to the infrequent operator.

A POCKET BOOK OF INFANT AND CHILDHOOD DIETETICS, with Directions for the Home Modification of Milk. By A. B. SPÄCH, A.M., M.D., Instructor in Medicine, Medical Department of the University of Illinois. Chicago: E. H. Colegrove, 1903.

THIS is a collection of formulæ intended to simplify the work of percentage feeding, together with two sets of blanks to be filled out and given to the child's mother. One blank is to be used for infants and the other for older children. The idea is a good one and well carried out.

DIE REKTO-ROMANSKOPIE AUF ANATOMISH-PHYSIOLOGISCHER GRUNDLAGE. Methodologischen Studien nebst Klinischen Ergebnissen und Hinweisen. Von Prof. Dr. JULIUS SCHREIBER. Direktor der. Königl. Med. Universitäts-Poliklinik zu Königsberg. Mit 3 Tafeln und Abbildungen im Text. Berlin: August Hirschwald, 1903.

THE author describes his instruments for proctoscopy, which are based upon those of Kelly, as is also his technique of examination. Detailed directions are given for the study of the rectum and lower portion of the sigmoid, together with observations on clinical material, and three colored plates illustrating diseases of the regions in question.

A TEXTBOOK OF MINOR SURGERY, Including Bandaging. By NEWMAN T. B. NOBLES, M.D., Professor of Surgery at the Cleveland Homeopathic Medical College, etc. Philadelphia: Boericke & Tafel, 1903.

INASMUCH as the author states in his preface that a book of this nature has not been printed in the homœopathic school for twenty-one years, we are quite willing to agree with him that the time is ripe for the appearance of such a manual. Its pages offer little that differs from the universally accepted principles of surgical practice, and we find advocated the same one-twentieth grain hypodermics of strychnine and one-fourth grain hypodermics of morphine that the older school is accustomed to give. The surgical teaching throughout is sound and made of value for every-day work by the addition of many practical suggestions, the result of the author's personal experience.

DIE DIAGNOSE AUS DEN AUGEN. Sowie Rationelle Gesundheitspflege und Krankenbehandlung. Von NILS LILJEQUIST, Zweite Auflage. Leipzig: Krüger und Co. 1903.

IF Oliver Wendell Holmes were writing an essay on medical delusions to-day, he would no doubt assign a paragraph or two to the medical curiosity afforded by the present volume, which assuredly is no less noteworthy to the student of human follies than were Perkins's tractors or Digby's powder. Together with a Hungarian named Peczely, the author claims to have discovered the fact that every disease and every trauma leaves its mark in the iris, and he has perfected a system by which the diagnosis of all morbid conditions may be made through a careful inspection of the eye, which he finds is not only the mirror of the soul, but also that of the body.

LA NATURE SYPHILITIQUE ET LA CURABILITÉ DU TABES ET DE LA PARALYSIE GÉNÉRALE. Par L. E. LEREDDE. Paris: C. Naud, 1903.

THIS brochure consists of seven chapters, in which are discussed the question of the syphilitic origin of tabes and general paralysis, based upon a critical analysis of the literature and the reports of illustrative cases. It is to a great extent an independent review and criticism of the original and pioneer work of Fournier. The author concludes that tabes and general paralysis in the syphilitic are syphilitic affections, and are curable by mercurial treatment if carried out systematically and in sufficient dosage during the early stage of the process. The last chapter is devoted to a detailed description of the method to be employed.

ESSAI SUR LA PSYCHO-PHYSIOLOGIE DES MONSTRES HUMAINS. Par N. VASCHIDE et CL. VURPAS (Asile de Villejuif). Paris: F. R. De Rudeval, 1903.

THIS little book contains a record of the history and microscopical investigation of the nervous system of an anencephalous male child. The life history of the well-known Siamese twin is also discussed in conjunction with a series of psychological experiments made by the authors. There are many interesting illustrations throughout the book, which concludes with an appendix by Doyen describing his recent operation for the separation of the Hindoo twins "Radica" and "Doodica."

FIRST PRINCIPLES OF OTOLOGY. A Textbook for Medical Students. By ALBERT H. BUCK, M.D., Clinical Professor of Diseases of the Ear, College of Physicians and Surgeons, New York City. Second Edition. New York: William Wood & Co., 1903.

IN this second edition the author has made the few minor changes necessary to bring matters up to date, and has placed the chapters on the anatomy and physiology of the middle ear and labyrinth in an appendix at the end of the book. The manual is a condensation of the author's well-known treatise on otology which has been so favorably received by the profession, several editions having been called for. It is well illustrated and well printed. We know of no better book to place in the hands of beginners in otology. It has the additional advantages of an excellent table of contents and a complete index.

ORGANIC NERVOUS DISEASES. By M. ALLEN STARR, M.D., New York, Professor of Diseases of the Mind and Nervous System, College of Physicians and Surgeons, Medical Department of Columbia University in the City of New York; Consulting Neurologist to the Presbyterian and St. Vincent's Hospitals, to St. Mary's Free Hospital for Children, and to The New York Eye and Ear Infirmary. New York and Philadelphia: Lea Brothers & Co., 1903.

THE statements in this book are based upon records of clinical and pathological material accumulated under the personal observation of the author. In a lucid and comprehensive style it imparts a general outline of the etiology, symptomatology, and treatment of organic diseases of the nervous system, and is fully up to date. Although the title implies a dissertation on organic nervous diseases exclusively, the subjects of neuralgia and spasmodic torticollis are nevertheless incorporated in the work. Upon the basis of the pathological findings in old cases of trigeminal neuralgia and neuralgia with herpes, the writer assumes that neuralgia has in every chronic case some organic lesion, while at the same time admitting (p. 79) that this is absent in acute and transient cases. As to spasmodic torticollis, he unreservedly admits (p. 689) that there are no pathological observations to determine its exact cause. The article on Multiple Neuritis comprises five chapters, taking up sixty-three pages, and is a valuable monograph in itself. In speaking of the etiology of tabes, the author says (p. 293) "while we admit that syphilis is a predisposing cause of the disease, we cannot consider tabes a syphilitic affection." We are pleased to note that this view is in accord with that of an increasing number of careful clinicians. The chapter on the Diagnosis and Location of Brain Diseases covers seventy-one pages, and the subject is presented in a very readable and masterly manner. There is also a special chapter devoted to the consideration of dementia paralytica (meningo-encephalitis).

In addition to many valuable references to the literature, the book is profusely and elaborately illustrated with photographs, original drawings, colored plates, and diagrams. Altogether it is a creditable exposition of American neurology, and will undoubtedly prove of great practical value not only to the undergraduate medical student and general practitioner but also to the neurologist.

A TREATISE ON THE CARE OF THE EXPECTANT MOTHER DURING PREGNANCY AND CARE OF THE CHILD FROM BIRTH UNTIL PUBERTY. By W. LEWIS HOWE, M.D. Philadelphia: F. A. Davis Company, 1903.

THIS little handbook is full of practical suggestions and will prove of great benefit in the care of the expectant mother. The author states that he lays no claim to originality. Such subjects as diet, clothing, exercise, and sleep, for the pregnant woman, are considered. In the latter part of the book the care of the infant is discussed.

# Society Reports.

## CANADIAN MEDICAL ASSOCIATION.

*Thirty-sixth Annual Meeting, Held in London, Ont., August 25, 26, 27, and 28, 1903.*

**Special Report to the Medical Record.**

*Tuesday, August 25—First Day.*

THIS proved one of the most successful meetings in the history of the association, both in point of attendance and interest. Besides guests, 275 members registered. London, the less, is a most attractive inland city of 45,000 inhabitants, fittingly named the "Forest City" from the profusion of its foliage. Wide streets and spacious lawns give the place an air of restfulness and comfort.

The arrangements for the meeting were most complete. The new Normal School in which the meeting was held is the finest building of its kind in the Dominion, and afforded ample accommodation and every facility for the convenience of the association.

The attendance numbered 325, including representatives all the way from British Columbia in the West to Nova Scotia in the East, as well as delegates and visitors from the neighboring republic.

The proceedings were conducted under the presidency of Mr. Moorhouse of London.

**The Surgical Treatment of Hallux Valgus and Bunion.**—Dr. JAMES NEWELL of Watford read this paper. He operated by a long internal incision, opening up the joint, with complete division of the ligaments. The tissues were separated from the joint, and the head of the metatarsal bone sawn through back of the cartilage. The exostosis was removed by bone forceps. Sutures were inserted, and the foot dressed. A sheet iron splint turned up at the big toe, padded, was applied and retained by a bandage. In ten days the sutures were removed and passive motion begun. The toe was kept in a straight splint for four weeks.

**Uterus and Adnexa in a Hernial Sac.**—Dr. FERGUSON of London presented a specimen of an incompletely developed uterus and appendages removed from the sac of an inguinal hernia. The external genitals and mammary glands were normally developed, but the vagina was a cul-de-sac without trace of cervix uteri or os. The patient was thirty-two years of age, married, had never menstruated, but at recurring periods of from four to six weeks was attacked with violent headaches to the point of distraction. She left the hospital twenty-three days after the operation, perfectly well, and during the four and a half months which had elapsed since her operation she had been absolutely free from the attacks of headache. The speaker considered that these attacks were due to ovulation taking place or being attempted under abnormal conditions. The frequency of congenital ovarian hernia he attributed to sexual confusion during fetal development, being analogous to undescended testicle in the male. He had been unable to find the special congenital defects present in this case reported elsewhere.

Dr. ECCLES of London commented upon the interesting and unique character of the case, and looked upon it as an interesting contribution to the literature of hernia.

**Typhoid Fever.**—Dr. W. P. CAVEN of Toronto opened the discussion on this subject. The conditions calling for active treatment, he said, were tympanites and hemorrhage. In the former he recommended turpentine and asafœtida, in hemorrhage, morphine. Sponging should be a routine in every case, with tepid water when the temperature was below 102°, with cold water when it was above that degree.

Dr. HERALD of Kingston would not employ internal medication in ordinary cases. In hemorrhage he considered the ice-bag as useful as morphine.

Dr. H. MCCALLUM of London lauded strychnine throughout the attack as the most important agent in the treatment of this disease.

**The Size of the Pupils as an Aid to Diagnosis.**—Dr. J. T. DUNCAN of Toronto read this paper. Bilateral contraction or dilatation or unilateral contraction or dilatation might render the pupils of unequal size. The diseased conditions associated with these abnormalities were described. Again the pupils might be contracted and fixed, contracted and movable, or dilated and movable or fixed. Further, they might be unequal and movable or fixed. The clinical significance of these conditions was pointed out. The size of the pupil as an aid to differential diagnosis was commented on, special reference being made to the diagnosis of locomotor ataxia.

**The Physiological Generative Cycle in Woman.**—Dr. JENNIE DRENNAN of St. Thomas read this paper. She held that evolution was incident to all forms of life. Adaptation to environment and heredity were factors in every phase of life. Structure was determined by function, and function was the product of environment. The functions of the female mammal were ovulation, pregnancy, and gestation. This cycle had become interrupted by ovulation and menstruation, as a result of adaptation to a pernicious environment. Accordingly improved environment would in time be the remedy to effect the restoration of the natural cycle.

**Gunshot Injury of the Humerus.**—Dr. HADLEY WILLIAMS of London reported and exhibited a case of gunshot injury of the shaft of the humerus and destruction of two inches of the musculospiral nerve. The case was seen by him four months after the accident. Non-union and complete paralysis were present. He dissected out the nerve, resected two inches of bone, and brought the nerve ends together by through and through silk sutures. Neither union of bones nor relief of the paralysis resulted. Four months after the first operation, he performed a second operation, in which he maintained the bones in apposition by means of a silver plate secured to the shaft as a splint by means of four silver screws. The nerve was separated from the bones by muscle tissue to protect it from compression by the callus. In six weeks the bones had united, and in nine months after the suture of the nerve ends the paralysis had disappeared and recovery was complete. The patient was presented for examination. The treatment of the case was original, and its essential points, the author thought, were the firm apposition of fragments by means of the plate and screws, the avoidance of tension on the nerve ends, the protection of the nerve from bony callus, and the apposition of the nerve-ends by through and through sutures.

**Two Cases of Hour-glass Contraction of the Stomach.**—Dr. HOWITT of Guelph reported these cases. One of the cases was complicated by an ulcer on the posterior wall of stomach, the other by cancer. In the former there was a history of gastric distress of thirteen years' duration. After operation the patient made a complete recovery, and gained fifty pounds in weight. The other patient, seventy-three years of age, recovered and lived for nearly a year in comparative comfort, being able to take solid food until a short time before his death.

**Operative Treatment of Hip Disease.**—Dr. ROBINSON of Ottawa reported two cases of operation for morbus coxæ, resulting in cure without shortening, although both cases had reached the abscess stage. The joint was opened up over the abscess in the usual way, and the success of the operation hinged upon attention to the following details: (1) Thoroughly clearing away of all diseased bone and débris; (2) careful preservation of all existing portions of periosteum; (3) stretching of the periosteum along the track of the old bone and its attaching to the periosteum of the lower margin of the acetabulum; (4) stretching of the muscles and fibrous tissue over the periosteum; (5) stretching of the leg full length, and application of

fifteen to twenty pounds for extension; (6) allowing the wound to heal by granulation; (7) letting the patient sit up in bed within two weeks after operation; (8) keeping the weight on for four months; or the use of a Thomas' splint, the patient being allowed to get up after six weeks; (9) prohibition of any attempt to walk for six months.

**Operation for Perforated Typhoid-ulcer.**—Dr. HUTCHISON of Montreal presented a report of five cases operated on for typhoid perforation. The fifth case only was successful. In it the operator used the left oblique incision. He believed with increased experience many of these patients could be saved. The rate of recoveries with operation was now 20 per cent.

**Address of the President.**—Dr. MOORHOUSE of London delivered the usual presidential address at the evening session. He dwelt upon the dignity of the profession, the *esprit de corps* which should characterize its members, the rewards and the trials of the work, the progressive character of medical science, the advances made in medical education in Canada with its high examination standards, the need of legislative enactments to insure Dominion instead of provincial registration, and the necessity of resisting the encroachments of charlatanism in all its hydra-headed forms.

**The Rôle of Eyestrain in Civilization and Medicine.**—Dr. GEO. M. GOULD of Philadelphia read this paper. Eleven alleged instances of this affection were gleaned from the history of the last century, including the names of Carlyle, De Quincy, Herbert Spencer, Parkman, and others —men of brilliancy and genius whose contribution to literature and science, vast as it was, was curtailed, in the speaker's belief, to a mere tithe of what it might have been were it not for the eyestrain from which he thought they suffered. The incalculable loss to the world which the author assumed to be attributable to this infirmity, and the unfortunate prevalence of eyestrain, demanded greater attention to the remedy of this ailment.

**A Lantern Lecture on the Open-air Treatment of Consumptives** was given by Dr. ELLIOTT, Superintendent of the Muskoka Sanatorium.

At the close of the lecture it was moved and seconded by Drs. Barrick and Powell, and supported by Rev. Dr. Moore of Ottawa, that the Government be urged to enact legislation providing for municipal sanatoria for consumptives. This motion was carried unanimously.

(To be continued.)

## AMERICAN CLIMATOLOGICAL ASSOCIATION.

*Twentieth Annual Meeting, Held at Washington, D. C., May 12, 13, and 14, 1903.*

*Tuesday, May 12—First Day.*

NORMAN BRIDGE, M.D., OF LOS ANGELES, PRESIDENT, IN THE CHAIR.

**President's Address.**—Dr. NORMAN BRIDGE, in his opening address, spoke on some dangers and duties of the American Climatological Association. He dwelt upon the importance of the study of air and water; he said that facts and not fancies were wanted, and that these facts must be found and recorded regardless of any use that might subsequently be made of them; but the facts should be used scientifically or not at all. The highest success of the association would never be reached till there was developed an avidity for scientific facts. This society in its travels from place to place had a variety of climates offered to it for practical study. To become scientific climatologists it was necessary to gather many facts, but, in the search for these, too often the air and its chemistry were forgotten, also the influence on the sick of its temperature, currents, moisture, and the daylight and sunlight passing through it. Too often generalizations were made as to the effect of climate, by its apparent influence on some sick newcomer, rather than on the permanent residents; we were apt to forget that these newcomers are under conditions and influences very different from those that they left at home, and where their sickness began. Some of the changes in these patients were doubtless due to climate, while others were possibly due to change of place, scene, occupation, cares, amusements, or experience. But we should not let our enthusiasm run away with our judgment and so ascribe impossibilities to some one good influence. Much harm was done by allowing hopeless consumptives and others to leave their homes and such assistance as was within their grasp, to travel perhaps long distances in a search for the impossible. Such cases as these were well known; and it was the duty both of the society and also of the general profession to protest against it. And those who could not be benefited by change of climate should be taught the value of proper hygiene, care and out-door treatment. It was only in the early stages that consumptives were benefited by change.

**The Climate of Nassau.**—Dr. S. A. FISK of Denver read a paper on this subject. He said that Nassau was a winter resort only, the season lasting from January to March. Among the advantages there was the negative one of getting away from the North; other places, such as Southern California, the Sandwich Islands, the Bermudas, the South Atlantic coast, and Jamaica offered this attraction; but they all had some disadvantages not shared by Nassau. Nassau was South, at the sea level, an island, and one hundred and sixty miles to sea. In many respects it resembled Colorado, only at the sea level and not a mile up in the air: as a result its barometric pressure was the one to which so many were accustomed. It had a dry soil of coral formation, good vegetation, pure air without dust, smoke, or atmospheric impurity, particularly when the wind blew from the north or east, which was the rule in winter, the air reaching Nassau only after passing over hundreds and hundreds of miles of the ocean. There was abundant sunshine with consequent out-door existence; slight wind velocity, and an equable temperature; the rainfall was large, about three or four times that of Colorado; heavy dews were encountered as in South California, but in Nassau there were no fogs. Colorado and Nassau offered a contrast, as follows: in Colorado there was a dry air, variable temperature, climate stimulating and bracing, and physical attractions of a rugged and mountainous character; while Nassau was at the sea level with dense moist air, equable temperature, climate soothing and enervating, and its attractions chiefly of the sea, such as fishing, sailing, and boating. The objections could be summed up in one word—tropical; but by proper regulation of diet, clothing, and exercise much discomfort could be obviated. Dr. Fisk summed up its advantages as a summer climate at midwinter; an ocean climate on dry land; brilliant sunshine, pure air inducements to live out of doors, and all at a sea level. He cautioned against sending patients with acute phthisis to Nassau, but recommended that climate for certain forms of heart trouble, Bright's disease, diabetes, neurasthenia, insomnia; also for those who either wanted a rest or were anxious to avoid a Northern winter.

Dr. E. J. A. ROGERS of Denver considered the paper invaluable; particularly because the writer knew what he was writing about, and possessed much practical experience in judging of climates.

Dr. H. SEWALL of Denver said that he had wintered in Nassau about twelve years ago, and the paper had vividly recalled his visit. He thought that the benefit of a change of climate was due to either the direct physiological effect, or to an indirect psychological effect; and that very often a short stay in a place was beneficial, while a long sojourn might be harmful.

Dr. S. E. SOLLY of Colorado Springs considered that the climate of Nassau was not good for patients suffering from acute pulmonary tuberculosis, but that chronic cases might be much benefited by a short stay, the sedative effect of the climate being good for the nervous system.

Dr. R. H. Babcock of Chicago, while interested in and instructed by the paper, was disappointed at hearing so little of the advantages and disadvantages of the hotels and boarding-houses. He considered this an important point, and that the association could do a great work in causing improvement in the accommodation afforded in certain places; he thought that the room, and table and toilet facilities should always be stated. All the physical advantages would not atone for bad accommodations.

Dr. Fisk thought that while it might be a good thing to emphasize these details, there was danger that if this were done the objectionable features might be dwelt on so long that every place would be neglected. He had grouped all the objections as tropical, and this included details of food, clothing, and toilet arrangements. The hotel accommodation was good but expensive; a simple boarding house was much cheaper, but might be a little dirty and without comfort.

**Some Further Remarks and Queries Concerning the Influence of Altitude on Heart Disease.**—Dr. Robert H. Babcock of Chicago was the author of this paper. He made brief mention of three cases of mitral stenosis which were able to endure an altitude of 6,000 feet without discomfort. He also reported the case of a female without previously recognized disease of the heart, who yet experienced an acute disturbance, which disappeared soon after reaching a lower level. He next mentioned the case of a miner who developed præcordial pain and tachycardia after considerable exertion, but whose symptoms were relieved at the level of Chicago. Allusion was also made to some cases of chronic nephritis which developed uræmic symptoms at the altitude of Denver. He would like to know if all these cases were capable of explanation on the same hypothesis. He, himself, did not know, but was inclined to believe that different factors were at work. In chronic nephritis, were the symptoms referable to a lowering of the blood-pressure or to increased metabolic activity? In the case of the miner, were the symptoms due to cardiac overstrain and not to the altitude *per se*? Could the effects in the other cases, good or bad, be attributed to lowered blood-pressure incident to low atmospheric pressure? Could any case of cardiac disease endure a moderately high altitude if the patient refrained from exercise until he became acclimatized? Since commencing this paper the writer had seen another case of mitral narrowing with patent foramen ovale of congenital origin; this patient had experienced no discomfort on taking exercise in the mountains of California; but on going to San Francisco she had promptly suffered from a severe attack of what was probably acute pulmonary œdema; this was apt to recur on exertion. Her blood-pressure though not very high was higher than normal. What was the explanation of this case? At first he had inclined to the belief that an abnormally high arterial pressure had something to do with it, but now he believed that the attacks of dyspnœa were of a mixed type, and that it required a condition of cardiac overstrain to develop the asthmatic tendency or pulmonary œdema, and when this was once established other influences were capable of initiating an attack. He would like to have an explanation of the points raised, and he would particularly welcome some statements concerning the mean blood-pressure in healthy individuals residing at an altitude of a mile or so.

Dr. DeLancey Rochester of Buffalo said that he had observed that mitral stenosis, particularly in female patients, was apt to be accompanied by neurotic tendencies. He believed that the myocardium was often at fault, and that if blood-pressure were studied much could be learnt of the condition of the heart. Attacks of dyspnœa were often the result of weakness of the myocardium due to changes in the arteries of the myocardium.

Dr. Beverley Robinson of New York had found that many patients were liable to suffer from nervous excitement and were easily influenced in this direction by adverse medical opinion. Many such patients had found that higher altitudes could be endured, and also be beneficial; therefore we should hesitate before nervously influencing such patients. Often, too, patients that we thought would be benefited in a high climate did badly, and their friends felt that we had given bad advice; possibly we were to blame.

Dr. S. E. Solly of Colorado Springs thought that the study of the blood-pressure was most important; he had known a case of aneurysm relieved at an altitude, if no undue exertion were indulged in, therefore he thought that blood-pressure must have some influence in these cases. The effect of change of climate was much greater on a patient's first arrival than ever after; but on arrival patients must not exert themselves, and at once place themselves under the care of a physician that they may be watched from the start. Overstrain was common in these cases.

Dr. E. J. A. Rogers of Denver said that those who practised in high altitudes had formerly been accustomed to send their cases of heart lesions to a lower level; now it was different, and he believed that it was the sudden change and not the high altitude that was beneficial. He reported a case of aortic aneurysm, of more than fifteen years' duration; at his advice this patient went, ten years ago, down to Missouri, but he could not live there, and soon returned to the mountains, saying that the altitude was paradise. A patient with contracted kidney was advised to go to South California; he went, got worse immediately, then rapidly sunk. He himself was personally conscious of change in arterial pressure, and often felt heart strain on injudicious exercise.

Dr. J. M. Anders of Philadelphia advised such cases to go slowly and to get accustomed gradually to changes. One case of his, of pulmonary tuberculosis, got well, while another one—cardiac—died. In high altitudes this might often occur on account of the physiological reserve being at a minimum. He believed that arterial tension was diminished at high altitudes, and that in chronic interstitial nephritis metabolism was stimulated by high altitudes.

Dr. Egbert Le Fevre of New York had observed two cases of mitral stenosis, in both of which the patients had been advised to go to high altitudes, and to avoid exertion; they did not do as advised. He found that drugs lowered the arterial pressure, but that when tension was lowered they suffered from cardiac pain.

Dr. Babcock was much pleased with the discussion and thought that cardiac lesions *per se* were not a contraindication to a high climate. A distinction ought to be made between mountain sickness and cardiac strain. He referred to the case of the late Dr. Byford of Chicago, who suffered from angina pectoris and could not walk in Chicago, but could do so at a high altitude. He agreed with Dr. Robinson that the nervous condition of the patient had much to do with what the patient experienced. He suggested the keeping of a register of blood-pressure, particularly in patients changing altitudes; in this way a large array of statistics might be obtained. He would allow any patient to go away to the mountains, on a promise to obey instructions.

**Studies of Bradycardia.**—Dr. Roland G. Curtin of Philadelphia read a paper with this title. He defined bradycardia as a condition, more or less transient, of pulse beat, more or less slow. As a rule heredity was not a factor in its production, but he had seen two such cases, both in drunkards. The textbooks were as a rule weak on this subject, but two notable exceptions were the treatises of Drs. Sansom and Babcock. Bradycardia was to be regarded as a symptom and not a disease. The condition was often seen in the febrile and post-febrile stages of influenza. He had pointed out that bradycardia was produced by the influenza poison. Cases were referred to illustrating this condition in influenza, lead poisoning,

Stokes-Adams' disease; it had also been observed after many of the acute infectious disorders, and in dyspepsia, chlorosis, anæmia, cerebral tumor, appendicitis, hysteria, nostalgia, malaria and seasickness. Hence bradycardia might be caused by a toxin in the blood, a narcotic poison, or anything interfering with the nutrition of the heart muscle. It seldom occufred in uncomplicated heart lesions.

Dr. EGBERT LE FEVRE of New York believed bradycardia was due to toxic influence; he referred to cases that had been benefited by drugs of the belladonna group. To try if artificial slowing of the heart would give bradycardia he had tried the galvanic current, with the result that the heart got so low that the patient became pale, but gradualy recovered under artificial respiration. He believed that bradycardia coupled with cardiac weakness might be due to excesses.

Dr. J. M. ANDERS of Philadelphia considered the paper both timely and important. In the case of the acute infectious diseases, he thought that a distinction should be made between the bradycardia due to the toxins and that occurring during convalescence, when it might be caused by mere exhaustion. This last was similar to that noticed after prolonged parturition. He had observed two cases of bradycardia in heart disease, but the trouble was probably referable to the myocardium; in cardiac cases bradycardia was more apt to be found in advanced lesions in which fibroid degeneration was present.

**Neuralgia in Relation to Altitude.**—Dr. F. S. PEARCE of Philadelphia was to have read a paper on this topic; but having come without his paper he reported two cases bearing on the subject. The first case was that of a young lady suffering with neuralgia, and who on moving to a lower altitude found that the attacks became less frequent and less severe. The other case was a physician of sixty years of age, whose neuralgia got worse when he went to Denver, but was improved on his returning again to a lower level. In neither of these cases was there any organic lesion found; but they were both neurotic.

**The Rôle of Local Sanatoria in Preventing the Spread of Tuberculosis.**—Dr. DELANCEY ROCHESTER of Buffalo read a paper on this subject. He said it was the general opinion of the medical profession that in the treatment of pulmonary tuberculosis the best results were obtained in sanatoria. He urged the establishment in every community of two sanatoria, one for advanced cases and the other for incipient cases of tuberculosis; and further, that all patients who could not occupy an airy room alone should be compelled to go to one of these sanatoria. Two sanatoria were necessary, because (1) the treatment of these two classes of cases was different, and (2) because the constant presence of advanced cases had a decidedly depressing influence upon incipient cases. He would further have all cases reported, and have the Board of Health send an inspector who was to decide whether the case was suitable for home or sanatorium treatment; every case was to be allowed the privilege of sanatorium treatment if so wished. He would give the boards of health, in cases of tuberculosis, the same powers that they now possessed in cases of smallpox, Forestalling the criticism that many consumptives might be able to attend to business and thus support their families, he urged that it would be found less expensive for them to quit work for six or even eighteen weeks and get well, than to continue to do rather poor work for even a year and then leave to quit for all time. Another objection which had been urged was that it was an unnecessary hardship to compel a patient to die in an institution and away from his family; to this he replied that such need not be the case, for the end was seldom sudden, and, as a rule, the friends could be notified. The bodies of all persons dying of tuberculosis should be cremated. He believed that some such plan of compulsory reporting of all cases, and compulsory removal of suitable cases to proper sanatoria, would be more efficacious than all other procedures in ridding the community of tuberculosis.

Dr. H. P. LOOMIS of New York thought well of the two classes of sanatoria, but did not agree with the element of compulsion. In New York it could not be enforced; and if the physicians would not do it, we could hardly expect the laity to. But there was another objection, namely that people did not want a sanatorium built in the vicinity of their property; they approved of sanatoria and were humanitarian, but did not want their property to be depreciated. The parallel between smallpox and tuberculosis he did not think good.

Dr. E. O. OTIS of Boston thought the idea of two sanatoria a fine one, but one that was not likely to be carried out. He was afraid that there would never be space enough or money enough to build them. He would like to ask Dr. Rochester how he would set about his work if reporting such cases were made compulsory, and how he would remove the patients, and how he would support the family of the patient during the illness and also after the patient's death.

Dr. E. L. SHURLY of Detroit said that hospitals refused cases of tuberculosis and sanatoria would take only incipient cases, hence the proper care of consumptives was a pressing question even from the standpoint of political economy. But he thought it was not the business of the State to provide sanatoria, for there would be enormous expense and taxation in connection therewith; then these sanatoria would be inseparably connected with politics. He thought that each community should take care of its own sick. He would ask: Can the State force physicians to give information? and, Are physicians custodians of the public health?

Dr. EGBERT LE FEVRE of New York wished to enforce the remarks made by Dr. Loomis with reference to reporting cases in New York. Soon after the New York Board of Health made it compulsory on physicians to report their cases of tuberculosis, a reaction set in, and many consumptives hid themselves because they were afraid of losing their places; they next suspected the practitioners, and asked if a report was going to be made, and the physician who said yes was not likely to see that case again! It was no use to compare the consumptive to the sufferer from an acute infectious disease. Why make our consumptives like the leper of old and yet give them no desert to go to? When boards of health would give definite advice and would agree not to visit the consumptive without the consent of the attending physician, then, and not till then, would physicians report all their cases of tuberculosis. He was against compulsory notification.

Dr. ROCHESTER advocated compulsory notification of disease; but thought that the visits of the Board of Health should depend on the wishes of the physician. The sanatoria that he advocated were local and not State. He would accommodate just those cases that could not be properly cared for at home; while those that had hygienic surroundings would not be compelled to leave their homes. In any event only suitable cases would be admitted.

Dr. OTIS asked what the accommodations for consumptives were at Buffalo.

Dr. ROCHESTER said they were very bad.

*Wednesday, May 13—Second Day.*

**Subsequent Histories of Arrested Cases of Tuberculosis Treated at the Sharon Sanatorium from 1891 to 1902.**—By Dr. VINCENT Y. BOWDITCH of Boston, This paper contained the subsequent histories of several consumptives for a number of years, with very full statistics, which it was impossible to epitomize.

Dr. E. O. OTIS of Boston wished to emphasize the value of such statistics and such papers; and he thought the thanks of the society were due to Dr. Bowditch for the immense amount of labor which the collection of those histories must have entailed.

Dr. NORMAN BRIDGE was sure that they were all under great obligations to Dr. Bowditch for the paper he pre-

sented. His work had added to their knowledge facts which they had long been seeking.

**Dispensaries for Tuberculosis, with a Description of the Tuberculosis Department of the Boston Dispensary.**—This paper was read by Dr. E. O. Otis of Boston. He said that in other countries dispensaries for ambulatory cases of tuberculosis were fairly common; while in this country they were few, and such patients generally attended a general medical clinic, where they received a variable amount of attention. In Boston a special department for these patients was started in 1899, as an experiment; at first it was only necessary for the physicians to attend two or three times a week, but now there was a daily attendance. With each patient there was a thorough investigation and examination; the history was gone into, the sputum examined, if necessary the tuberculin test and *x*-rays were invoked. When the diagnosis had been made, district nurses went to investigate the home conditions of the patient; this included sanitary, personal, social, and financial conditions. A brief circular of information concerning the sputum and general hygiene was given; and the patient was furnished with the necessary medicine either free or at a cost of ten cents. If the case was an incipient one an endeavor was made to get the patient into the hospital at Rutland; while the more advanced ones were recommended to one of the small extra-mural sanatoria outside the great sanatorium at Rutland. At the clinic patients were also examined who had left the Rutland sanatoria, and who had taken the outdoor treatment elsewhere; thus the dispensary both preceded and completed the sanatoria. After describing the equipment desirable for such a dispensary, the writer went on to indicate what, in his experience, were the objects of such a dispensary: (1) As complete an investigation of the patient as possible, including history, physical and bacteriological examination. (2) Investigation of the patient and his surroundings at his home, including the hygienic conditions of his house. (3) Instruction, both of the patient and his household, in hygiene and the safe disposal of the sputum. (4) The free supply to poor patients of pocket- and house-spittoons. (5) Securing entrance into sanatoria for curable cases, and into consumptive hospitals for incurable ones who could not be properly cared for at home, and when both of these were impossible in providing home treatment. (6) Aiding poor patients to obtain suitable food and other articles necessary for their proper care. (7) Affording an opportunity to physicians to send their poor patients for diagnosis when desired, as well as for advice and assistance in treatment. (8) Opportunity for scientific study and investigation of tuberculosis. (9) Clinical instruction to students and physicians in the examination of tuberculous patients.

Dr. DeLancey Rochester of Buffalo had not been able to establish such an institution at Buffalo. He understood Dr. Otis to say that he used the tuberculin test on these ambulatory cases; he would like to ask how the temperature was taken, as he (the speaker) was in the habit of taking it every two hours. He was still in favor of two local sanatoria.

Dr. J. Daland of Philadelphia was much struck with the uses to which such a dispensary could be put. He considered that tuberculous cases required and deserved much time.

Dr. L. Weber of New York emphasized the value of home treatment, and believed in the establishment of hospitals for consumptives.

Dr. A. C. Klebs of Chicago thought that a great point in the work of such a dispensary was the help afforded the family. In Chicago they had just inaugurated an association that was to gather information about the consumptives, both clinical and statistical; and also to put itself in communication with other places; food and employment would also be furnished to the sufferers when necessary. He thought oral instruction in hygiene superior to printed circulars on the subject.

Dr. F. I. Knight of Boston thought that the visits of the nurses to the houses of the poor were of great value. In Boston they had an association (of which Dr. Otis was president) which provided for this very thing.

Dr. J. E. Stubbert of New York thought that these dispensaries did good work. In New York 93 per cent. of the consumptives could not leave the city, and so sanatoria alone would not solve the problem. Dispensaries reached the incipient cases that could be benefited. The greatest results were from hygiene and food, not from medicine. He would suggest a combination of the dispensary and hospital, where the patient could attend to his work and still be treated for his disease.

Dr. C. E. Quimby of New York thought that now the treatment of tuberculosis was being placed on a proper and rational basis; and he wished to congratulate Dr. Otis, and all of those who had started with the district nurse.

Dr. Otis said with reference to the tuberculin test, that he was the first to adopt it in ambulatory cases; of course that was not the ideal plan, but still it gave good results.

**Tent Life for Consumptives.**—Dr. J. Edward Stubbert of New York read this paper. (See page 13.)

Dr. C. L. Minor of Asheville, N. C., regretted the tendency to suppose that the ordinary tent would fulfil the conditions for open-air treatment of tuberculosis. His experience was that the ordinary tent allowed less air than was desirable. He thought that the German system of barracks or cabins around the sanatoria allowed better ventilation and ample cubic contents of air. It seemed to him that the fresh-air treatment might be pushed so far as to terrify the general public.

Dr. F. I. Knight of Boston agreed with Dr. Minor with regard to the insufficient cubic capacity for air in tents generally. He preferred barracks or cabins. It seemed to him that the air in the few tents in which he had been was the worst possible for consumptives.

Dr. E. L. Trudeau of Saranac Lake, N. Y., suggested that one of the main difficulties to be overcome in the tent treatment was the providing of the maximum amount of sunlight.

Dr. S. A. Fisk of Denver emphasized the great necessity for fresh air. He knew from his own experience that persons could live in tents in midwinter, and that when one had become accustomed to living and sleeping in a tent he did not care to live in anything else.

Dr. Stubbert, in replying, said that he agreed that the ventilation in tents was often poor, but still it was usually superior to that of the rooms used by the patients. He thought that a tent, when used, should be opened sufficiently to provide proper ventilation. He agreed with Dr. Fisk, that a person who had once lived in a tent would live in nothing else.

**The Syphilitic Diseases of the Heart and Aorta.**—Dr. Leonard Weber of New York read this paper. He referred to the frequent occurrence of syphilis in diseases of the heart and lungs. As to the etiology, he said that old syphilitics not properly treated, or quitting treatment, are somewhat apt to develop visceral lesions, and that the vigorous had as little guarantee against coronary sclerosis as the feebly constituted. In tabes dorsalis aortic insufficiency had occasionally developed, but it was produced by the syphilitic virus and not by the posterior sclerosis. He believed in a causal connection between syphilitic lesions and certain cases of chronic diffuse and interstitial nephritis dependent upon arteriocapillary sclerosis of the kidney. At the autopsy of a syphilitic heart or aorta there was nothing to distinguish the arteriosclerosis of syphilis from that produced by other causes, except the gumma. The diagnosis was difficult except for the syphilitic stigmata; the history was unreliable, but the therapeutic test was good. The anatomic material was not yet sufficient to build data on. The

treatment was beneficial even if a cure were not effected; iodide of potassium alone was not sufficient; mercurial inunctions or the bichloride given hypodermically proved serviceable, and the general nutrition required attention.

**A Cabin for Open-air Treatment.**—Dr. R. A. CLEEMANN of Philadelphia read a paper with this title. He said that tuberculosis flourished among dwellers in houses, while with an out-door life many recovered, most houses being insufficiently ventilated. Tents had been tried, but they soon became offensive if the end flaps were not opened and the walls systematically raised. The tent's shortcomings were shown by the many attempts to improve its ventilation; but these same devices had been unsuccessful in keeping tuberculosis out of houses. Ventilated tents were an improvement on ordinary houses, but a specially devised cabin was, he thought, an improvement on the tent. Such a cabin was described, and plans and illustrations shown. The chief feature was a movable wall; when three sides were lowered and the folding doors opened, the space before enclosed was at once flushed with fresh air and flooded with sunlight, while the walls themselves were placed in a position to receive on their interior face the rays of the sun. Spaces above the walls allowed ventilation, and these spaces could be closed in the coldest weather and during rain storms. The chief objection in a Northern climate was the cold, but this could be obviated by a stove. The cost of a cabin for one or two persons was about two hundred dollars.

Dr. S. E. SOLLY of Colorado Springs asked if the walls were solid or hollow. Dr. Cleemann said they were solid. Dr. Solly said that he was in favor of a hut with hollow walls, as a more equable temperature could be maintained. He also suggested that it would be an advantage if the walls were raised like the wings of a tent; and further that it would be very useful to have these huts made so as to revolve, thus permitting any portion to be turned to or from the weather. The advantage of the hut over the tent was that in the former the heat and cold were kept out much better.

Dr. C. MINOR of Asheville inquired if the cottage described was at present on the market, and if so at what price. An ordinary carpenter could not be induced to make such a cottage properly and economically.

Dr. CLEEMANN said that the sides were not planned to be raised up, because such a procedure would interfere more or less with the ventilation, and also that the sun would not have the same free entrance. In answer to Dr. Minor, he stated that the price placed on such a cabin was only his personal estimate, as these cabins had not yet been tried. He thought that an ordinary carpenter could make one for one hundred and fifty dollars; he had been asked as much as two hundred and seventy-five dollars, but that was excessive.

**Tuberculosis in the Negro.**—Dr. THOMAS D. COLEMAN of Augusta, Ga., read this paper. He said that in the South, tuberculosis was on the increase among the negroes. Before the war it was rare to find a case among that race, and some writers considered the negro almost, if not quite, immune. He presented statistics showing percentages of deaths of whites and of blacks from tuberculosis during a period of five years. These figures showed in Charleston the proportion dying of tuberculosis was, whites, one in eleven; colored, one in six: in Augusta, whites, one in eleven; colored, one in six; and this record demonstrated that though the colored population was 10 to 16 per cent. less than the white, in five years tuberculosis carried off 147 white persons, and 448 colored. In round numbers, and allowing for discrepancies, there die annually from tuberculosis about twice as many colored people as whites. The reasons of this, he believed, were as follows: That in slavery the negro had an open-air existence, was free from care, while now he was independent and his habits and mode of living had undergone a radical change. Tuberculosis in the negro was due largely to his mode of life, more so than to any racial peculiarity; hygiene was unknown to the negro, his morals were lax, his hours irregular, and hence his constitution was depleted, and he was more apt to fall a victim to the disease. At the autopsies on all negroes dying in the Georgia Insane Asylum in 1901, over 50 per cent. showed evidence of tuberculosis. Venereal disease also weakened the negro, and though some observers had stated that syphilis protected the individual against tuberculosis, he could neither commend it as a prophylactic nor verify it as a fact. As a remedy he suggested: cooperation of both races; hygiene; and that local boards of health should exercise their educational influence, superintend the disease, and disinfect every house in which tuberculosis occurred.

Dr. E. O. OTIS of Boston inquired if Dr. Coleman had collected any statistics with reference to the number of tuberculous whites in insane asylums, as compared with similar hospitals for negroes.

Dr. T. DARLINGTON, Jr., of Kingsbridge, New York, said that his experience bore out the facts presented the paper read. He said that he had found the negroes under his care very suspicious in regard to medicines, and that 100 per cent. of them had syphilis.

Dr. T. J. MAYS of Philadelphia remarked that about four or five years ago he had looked into the relation between consumption and insanity in the negro. He had found that, before the war, insanity was rare and consumption practically unknown. Since the war the negro had required insane asylums, and afterward developed consumption. He believed that insanity came first among the negroes, then probably syphilis, or possibly syphilis preceded insanity, and then came tuberculosis.

Dr. C. L. MINOR of Asheville took issue with one point in the paper, he did not think there was any racial susceptibility. The disease was prevalent among the colored race on account of their surroundings, occupations, mode of life, etc. Before the war the negroes had abundance of good food, regular hours, and quarters carefully looked after; now their quarters were abominable, their food worse, and their hours irregular.

Dr. S. BROWN of Chicago thought that pure air and ventilation were the main things to be considered. He referred to the British army and navy as an illustration of the almost total disappearance of tuberculosis in the presence of proper ventilation. The boards of health, in their publications, were prone to wander from the essential things, such as ventilation, and talk about germs and spitting on the floors, etc.; he thought this was wrong and should be corrected.

Dr. E. R. BALDWIN of Saranac Lake, N. Y., took issue with Dr. Minor on racial susceptibility; he believed it existed.

Dr. COLEMAN was sorry that he could not answer Dr. Otis' question. With reference to Dr. Darlington's statement about the timidity of the negro in taking medicine, he thought that fear was only developed in the North, for in the South nothing pleased the negro more than an abundance of medicine. With reference to Dr. May's figures, he would place syphilis first (about 75 per cent.), tuberculosis second, and insanity third. He thought that Dr. Minor's question about racial susceptibility had been answered by Dr. Baldwin, and also by the statistics that he (the writer of the paper) had given.

**Some Experiments in the Treatment of Pulmonary and Laryngeal Tuberculosis by Means of the Electric Light.**—Dr. W. C. GLASGOW of St. Louis read a paper with this title. He described a few experiments which he had been making with the electric arc light in cases of pulmonary and laryngeal tuberculosis, and showed the effect which exposure to the electric arc produced in the pathological processes, and the changes made in the physical signs due to this exposure. These changes were: diminution of secretion in the cavities, relief of pain, and general improvement of nutrition. He believed that such radical

and rapid changes toward improvement had not been observed under other forms of treatment. The results produced were similar to prolonged residence in the West, but only required months instead of years. He reported a number of cases in which benefit had been produced in pulmonary conditions in a short period; and he believed that, under proper conditions, no danger was likely to occur.

Dr. De Lancey Rochester of Buffalo was much interested in the paper because for the last two years he had been experimenting with electricity on the consumptives in the Erie County Hospital. He had used the actinic rays, and obtained absolutely no beneficial results. In his experiments the chest only was exposed to the rays, and the sittings were not nearly so long as those spoken of in the paper. He asked for details as to the manner of application, and whether applied to the whole body, or to the chest alone.

*Thursday, May 14—Third Day.*

**A Discussion on "The Community and Tuberculosis."**—This discussion was opened by Dr. Beverly Robinson of New York, who read a paper on the subject. He said that health boards and physicians were now coöperating to help consumptives. He believed that two sanatoria should be employed, one for the well-to-do, the other for the poorer, so that they might end their days in comparative comfort. Sanatoria should be under proper control; that for the poor meant cure for many and consolation for many more; for when those who had been inmates returned to their homes, whether improved or not, they were apt to educate others in matters of hygiene. Home treatment was the only one that was at present available in New York; about one thousand could at present be accommodated in hospitals and sanatoria, and accommodation was required for ten or twenty times that number. Specific drugs were not in much demand now, but what was very much needed was an anti-tuberculous serum that was absolutely reliable. For the poor, better food, hygiene and improved tenements were wanted; these, with proper information given to the patient, would mean increased resistance to the disease. In attempting to help the community there was no need to label and punish the patient, and make him a social outcast, he was already suffering enough. Much help could be rendered at home, and much useful advice given. Tuberculosis was not contagious in the ordinary sense of the term, but it was infectious and communicable. The mortality was steadily decreasing. The treatment suggested by the ignorant was often inhuman, for example the attempts to keep out consumptive immigrants; but fortunately this method had been opposed by the more humane of the medical profession. The needs at the present day were proper hygiene, prophylaxis, disinfection, and disposal of sputum. As a rule tuberculosis would not be taken except on a susceptible soil. The writer stated his own personal experience, of over thirteen years, in the New York Hospital, and during that time neither he nor any one of his assistants contracted the disease, and in those days the disinfection was not the same as obtained to-day; yet he had never heard that the New York Hospital was a center for the spread of tuberculosis. He believed that tent life was the proper and perfect life for consumptives, particularly for incipient cases.

Dr. F. I. Knight of Boston said that there was no doubt that tuberculous patients would recover under all conditions and whether treated or not; of course more recovered under proper modern treatment in sanatoria. The chief thing was for the patient to be away from home, and this was particularly the case when the patient's home was in a cold climate. The tent treatment he had no sympathy with; he had never seen a tent that was comfortable; in summer it was too hot, and in winter the air was foul.

Dr. E. O. Otis of Boston said that Dr. Robinson had seemed to disparage private sanatoria; but there were two points that should be remembered in this connection: one was that the patient could be controlled far better in such an institution than was possible at home even under the most favorable conditions, and the other was the educative influence of these sanatoria. With regard to the cruel treatment accorded in many cases, he thought that the profession was largely to blame in the matter; undue fear was created by the placards in the street cars and elsewhere, prohibiting spitting, while no attention was paid to pure air or ventilation.

Dr. S. E. Solly of Colorado Springs agreed that to take the patient away from his home, even if only a few miles, was a valuable proceeding. He thought that barracks would prove better than tents, particularly as in the latter it was so difficult to maintain an equable temperature. The rule should be to send consumptives away from home, to keep them out of doors, not in a tent but on an open porch attached to a hut for the poor, and a better house for the rich. Another advantage of sanatorium treatment over home treatment was in suggestion; patients would do what they saw others doing.

Dr. DeLancey Rochester of Buffalo said that unfortunately many cases were among the poor who could not go away from home, and here the suggestions made in the paper were valuable. In Buffalo, even with an unsuitable climate, many of his patients had adopted an out-of-door mode of life, and many of them had improved and some had recovered. He thought that the chief difficulty was with the dwellers in tenements, often with dark rooms and no windows to the sleeping rooms; such cases he urged should be compelled to go to the proper place of treatment, namely the sanatorium; and that they should stay there until it was safe for them to return home.

Dr. T. Darlington, Jr., of Kingsbridge, said that in handling these cases the physician had four duties: (1) his duty to the family of the patient, (2) to the patient himself, (3) to the community, and (4) to the neighborhood to which he proposed to move the patient. In New York it was an absolute impossibility to get fresh air into the tenement houses; and the only thing to be done with the consumptives was to move them away. But how was this to be done? The consumptives could not go to any part of the State without the consent of the supervisors of that county; and the erecting of a colony of tents for these people was hardly feasible, for there was no room in the city and they could not get out of the city. It would injure the well and healthy to allow the consumptives to settle where they pleased.

Dr. R. C. Newton of Montclair, N. J., thought that it was very little use to pick out here and there a very good tenement-house man who wanted to be healthy and to take him off somewhere, or to put in his house a "marble bath tub." We were unable to do much good unless we reformed the general condition, and that was the problem that confronted us.

Dr. R. A. Cleemann of Philadelphia thought that the difficulties were much exaggerated. The solution of the question was simple, namely to get the people out of their homes and under the care of some institution controlled by the State. He thought that eventually the cities would reserve in their neighborhood a lot of ground not covered with houses, on which could be erected not a tent city but a barrack city.

Dr. R. G. Curtin of Philadelphia did not think that tuberculosis was as contagious as many physicians appeared to make it, and he mentioned cases in support of his view. He thought that at the present time consumptives were more studiously avoided than if they were lepers.

Dr. C. L. Minor of Asheville thought that the profession had been too enthusiastic; it had educated the public foolishly and now ought to try to educate it in the right way. After the tubercle bacillus had been discovered some men could see nothing but bacilli.

Dr. T. W. Harvey of Orange said that twenty years

ago, among the hatters, two diseases were very prevalent:—chronic mercurial poisoning and tuberculosis. At the present day, in better ventilated houses, it was a rare thing to see chronic mercurial poisoning, and tuberculosis was no more common among the hatters than it was among other classes of workers.

Dr. R. H. Babcock of Chicago understood the paper as an argument against sanatoria for poor consumptives; he would like to point to the attitude of the Germans as an argument in favor of such sanatoria. If the people were properly educated there should be no greater difficulty in getting sanatoria and hospitals for the treatment and segregation of consumptives than in getting hospitals for surgical cases. The next best plan was the dispensary treatment, as described by Dr. Otis.

Dr. Beverley Robinson said that there was a great deal that had been said in the discussion that he agreed with, and much with which he disagreed most absolutely. The public had been put wrong and the medical profession should put the public right again. Sanatoria were doubtless all right for the few, but we could not take care of the majority in that way. Our cities should be made habitable and then a great amount of disease would disappear.

**The Death Rate of Acute Pneumonia.**—Dr. Thomas J. Mays of Philadelphia read this paper. He said that the way to gather statistics that would be of service was to gather them from as wide an area as possible. The figures quoted in the present paper were from various health boards. He presented charts showing the death rates from phthisis, pneumonia, and heart disease in Philadelphia, New York, Chicago, Boston, St. Louis, Buffalo, District of Columbia, Rhode Island, New Jersey, Richmond, Va., Baltimore, Reading, Pa., and also a composite chart. His conclusions were that there was no good reason for believing that pneumonia need cause present or future alarm; that its highest death rate occurred before 1896, and that since that time it had declined 21 per cent.; compared with heart disease, pneumonia ranked rather low. Further, that there was a reduction in the death rate of phthisis in all of the localities referred to; and that the average decrease in phthisis was from 2 to 3 per cent. a year. On the whole he concluded that deaths from pneumonia were decreasing; deaths from heart disease were increasing; and that deaths from phthisis had been decreasing until five years ago, but that since that time they had markedly increased.

**The Complications of Pneumonia.**—Dr. Thomas G. Coleman of Augusta, Ga., read this paper. He considered that at the present day the diagnostic methods were probably better and more accurate than formerly; and also that cases were more often reported before societies; hence figures with regard to these cases probably had some value. Pneumonia, if uncomplicated, was amenable to treatment. Complications were serious. The commonest complication was pleurisy, generally of the dry plastic variety, but there might be effusion, either little or much. In the earlier stages there was more pain than in the uncomplicated disease. Other serous membranes were also liable to infection, and so there might be endocarditis and, less frequently, pericarditis. Myocarditis was sometimes present. He reported a case of pneumonia which had been complicated by gangrene of the lung. Other complications were meningitis, venous thrombosis, thrombosis generally, embolism, and very rarely acute nephritis. The lesson of these complications was that eternal vigilance was the price for the life of the patient.

**Seasonal Prevalence of Pneumonia.**—Dr. W. F. R. Phillips of Washington read this paper. He presented statistics of sixteen cities. In most cities the mortality rose with the fall of the temperature, and reached the maximum in the coldest part of the year, December and January; then it fell, and then rose again to a second maximum in March or April. Sometimes the first maximum was the greater, and sometimes the second was. He simply stated this as an interesting fact, and would like an explanation of that rise, followed by a fall, and then succeeded by another rise.

**The Treatment of Pneumonia.**—Dr. G. R. Butler of Brooklyn read a paper on this subject. He said that in pneumonia improvement would sometimes occur under any treatment or no treatment; that death would sometimes intervene in spite of any treatment; and that in a third class of cases the result depended largely on the doctor. The mortality in pneumonia was about the same as formerly, the apparent increase being in the disease. Unfortunately there was no specific for pneumonia; but several factors had to be considered in treating this condition, the chief of these being: age, the previous condition of the heart and kidneys, the virulence of the infection, and the resisting power of the patient. Probably an antitoxin would be discovered capable of effecting a cure. One thing that often hindered proper treatment of the disease was insufficient consideration of its possible duration. There was need to remember that mild and uncomplicated cases might later on become severe. The patient required good ventilation, not too much bed-clothing, rest, and to be kept in the recumbent position; too much physical diagnostic zeal on the part of the physician was to be deprecated. The diet was to be of milk and broth; and the kidneys and intestines were to be kept flushed out. For medicines, he recommended calomel at the onset; quinine, in seven or eight-grain doses, and preferably hypodermatically. Carbonate of creosote was good, in that there resulted a better fever curve and less toxæmic symptoms; pain was to be relieved. In the graver cases, delirium, restlessness, and insomnia were complications. He thought that the temperature should be let alone unless it rose to 105°; tubbing he considered unjustifiable except in children, but a cold rubbing down he believed beneficial; tympanites was to be watched for, but was less likely to be present when carbonate of creosote was administered. He would suggest as little active treatment as the case would allow; but he did not advocate sitting by with folded hands.

Dr. Rochester of Buffalo said that in diseases like pneumonia, in which we had no specific, we should note nature's way of bringing about a recovery, and also note the way in which the patients died so that this latter could be prevented. Nature's methods for recovery were a profuse sweat at the time of the crisis, and sometimes a critical diarrhœa; when a patient died it was almost always through failure of the heart or some heart complication. He gave a saline laxative daily, to keep the bowels open, in addition to the initial dose of calomel; he also gave a hot mustard foot-bath; this was followed by an alcohol rub to keep the sweating from continuing too long; the heart he supported by strychnine.

Dr. J. Daland of Philadelphia was of opinion that the high mortalities quoted for pneumonia were from hospitals and not from private practice. He thought that as death was likely to occur through the heart, the poultices and cotton jackets should be excluded, so that there might be more frequent examination of the heart with the least disturbance of the patient. In this disease the coagulability of the blood was very great, so that with a weak heart cardiac thrombosis was probably one of the common causes of sudden death. Venesection, he thought, was indicated in this condition, and the existence of a weak pulse at the wrist was no contraindication to the removal of from sixteen to twenty-four ounces of blood. Alkalies, preferably in the form of alkaline waters, would diminish the coagulability of the blood; the same effect was produced by milk. He agreed with the salines and calomel throughout the disease; and also recommended the careful study of the heart.

Dr. W. J. Barlow of Los Angeles said that in Southern

California they seldom saw the serious cases of pneumonia common in the colder climates, and perhaps this would explain the lower death rate of pneumonia in California.

Dr. E. Le Fevre of New York had found that the cases of cardiac failure were of two kinds—one in which the heart muscle was weakened, and the other in which there was a vasomotor paralysis and dilatation of the blood vessels resulting in collapse and probably due to the direct action of the toxins on the vascular center. In the first class of cases he gave diffusible stimulants, such as the salts of ammonium, and also some drug of the digitalis group, preferably strophanthus. At present, in New York, there was a craze for inordinate doses of the nitrites and nitroglycerin for combating heart failure in pneumonia, and in some cases in which death was due to vasomotor collapse he believed that these drugs had hastened the end.

Dr. J. W. Brannan of New York said that reference had been made to statistics published by enthusiastic observers showing a very low mortality under special lines of treatment. He narrated his experience in following a special treatment that had been recommended in a paper some six or eight years ago. This method consisted in taking several bricks, immersing them in hot water, wrapping them in hot blankets, and then placing them around the patient; but the speaker could not claim any great success with this plan.

Dr. T. Darlington, Jr., of Kingsbridge called attention to the fact that both nitroglycerin and ammonia had been used as stimulants, and that sometimes they had been combined; but they were absolutely incompatible, and so it was evident that if any effect was produced, one of them must have been in excess of the other, and to this excess the effect was limited.

Dr. H. L. Elsner of Syracuse said that it was known to pathologists that the pneumococcus toxin paralyzed the spinal center, and that the chances were that we had an interference with the central blood circulation in pneumonia, practically giving us a vasomotor paralysis. He believed that much harm had been done by the indiscriminate use of the nitrites in these cases. One of the best remedies, and it had not been mentioned, was sparteine, in doses of one or two grains every two or three hours; also adrenalin or suprarenal extract; each of these would stimulate the right heart, and that was indicated in pneumonia. He believed that the diffusible stimulants were indicated in all cases of cardiac failure in pneumonia, but they must be given at short intervals. Pneumonia was a disease requiring polypharmacy and persistent effort on the part of the doctor and nurse.

Dr. S. E. Solly of Colorado Springs briefly referred to a case of pneumonia that he had successfully treated on the cold-air plan.

Dr. R. G. Butler of Brooklyn regretted that his paper had been so long that it had been impossible for him to deal with the most important complication of all, namely the weak heart. If the paper seemed to insist a little too strongly on the importance of treatment in pneumonia, it was because it was written while he was still under the impression of three cases seen in consultation. The physicians in attendance were all therapeutic nihilists, and he believed the patients were being allowed to drift to death; but under proper therapeutic treatment they recovered.

Dr. T. J. Mays of Philadelphia believed that we overrated the treatment of the heart in pneumonia. As between the lungs and the heart, the heart was the older organ of the two, and therefore was the more resistant; he thought death usually came from the lungs.

**A Case of Tuberculous Bronchiectasis.**—Dr. S. E. Solly of Colorado Springs read a paper on this subject. It contained a very full report of a case of this rare condition, with skiagraph illustrations. He believed that a clearly marked bronchiectasis in a case of tuberculosis was nearly always an old chronic case of fibroid phthisis, in which the fibrosis was so extensive as to cause dyspnœa upon even moderate exertion. The case reported had quite unusual features.

Owing to the late hour no discussion was invited.

**Studies in Deep Breathing.**—Dr. Richard C. Newton of Montclair, N. J., was the author of this paper. He discussed the advisability of allowing deep breathing to phthisical patients and inquired what rules should be formulated to make pulmonary exercises beneficial to consumptives. The value of deep breathing for the non-phthisical being allowed, he inquired: (1) How early should we commence with it in children? (2) Was it not better to encourage small children to aërate their lungs by running, or climbing? (3) Could we expect to get help from it in the aged? (4) Would it not be well if every one practised it regularly? He thought that deep breathing might help in a number of pathological states, as asthma, gout, lithæmia, cholelithiasis, obesity, anæmia, and heart disease. It might also be of value as a prophylactic against pulmonary tuberculosis.

**The Cyrtometer; a Neglected Instrument of Pulmonary Diagnosis and Prognosis.**—This paper was read by Dr. Charles L. Minor of Asheville, N. C. He said that new instruments were replacing old ones, but that the cyrtometer was an old instrument that was of much use both for diagnosis and also to show the progress that was being made either by the patient or the disease. He described in detail the application of the instrument, illustrating his method with examples and charts.

Dr. Guy Hinsdale of Philadelphia demonstrated a double stethoscope devised by Dr. Wetherell of the Naval Service. The object of this new stethoscope was to mark differences in pitch on the two sides of the chest, and also for auscultatory percussion.

In the afternoon the concluding session was held in the lecture hall of the Columbian University. Dr. Judson Daland of Philadelphia spoke on "Leprosy in the Hawaiian Islands." The lecture was illustrated with lantern slides.

Mr. Gilbert McClurg of Colorado Springs read a paper on 'The Topography and Climate of the Pike's Peak Region." This paper was illustrated with lantern slides.

## Books Received.

*While the* Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Clean Milk. By S. D. Belcher, M.D 16mo, 146 pages. Illustrated. The Hardy Publishing Co., New York.

Handatlas der Anatomie des Menschen. By Wilhelm His. Third Volume, Second Part, 4to, 839 pages. Illustrated. S. Hirzel. Price, M. 13.

### POST-TYPHOID SEPSIS.*

By FRANCIS DELAFIELD, M.D.,
NEW YORK.

TYPHOID fever, as a disease, regularly lasts for four weeks, with periods of improvement at the end of the second and third weeks. These periods of improvement may be permanent, so that we have two-week, three-week, and four-week typhoids. If after the expiration of these periods the patient has fever, it is usually not typhoid fever, unless there is a true relapse. A true relapse is a fresh attack of typhoid fever.

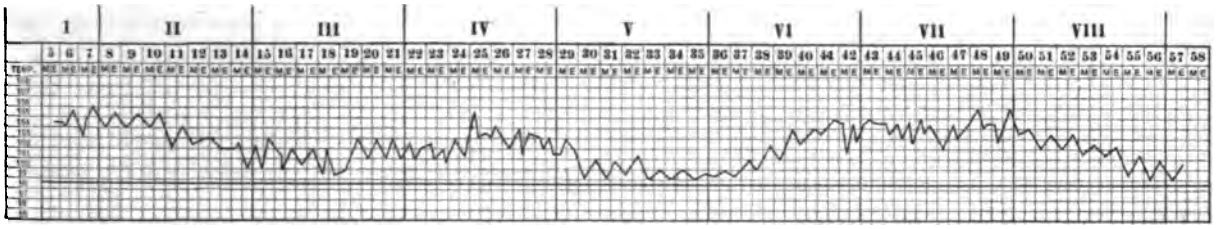
When a person suffers from a bacterial infection this does not by itself make a disease. The disease is one complex product of the bacterial infection and the various morbid changes that go with it. To make up a true typhoid fever there go together the bacterial infection and the intestinal lesions. When these have run their course other things may happen, but they are not typhoid fever. There may be inflammation of the gall-bladder, of the urinary bladder, of connective tissue—all due to infection with typhoid bacilli, but they are not typhoid fever.

In the same way, after typhoid fever there are fevers which may be due to typhoid bacilli, or to other infections, but they are not typhoid fever.

It is to these post-typhoid fevers that I wish to call attention.

We must first distinguish the true relapses, which are really fresh attacks of typhoid fever with the regular features of the original attack. The interval between the end of the original attack and the beginning of the relapse is from three to twenty-five days. The relapse lasts from seven to thirty-nine days. A single relapse is of ordinary recurrence; a second relapse is comparatively rare.

Chart No. 1 shows a typhoid of four weeks' duration, an interval of seven days' duration, and a relapse of seventeen days' duration.



No. 1

Chart No. 2 shows a typhoid of eighteen days' duration, a first interval of twenty-three days, a first relapse of seven days, a second interval of eleven days, and a second relapse of seven days' duration.

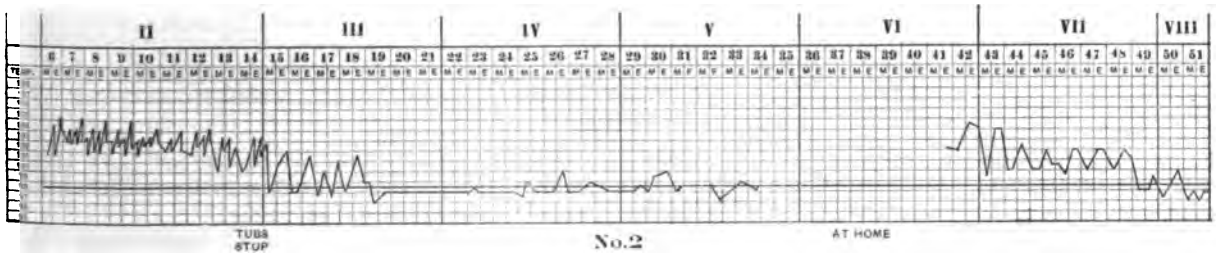
Now, if we turn to the post-typhoid fevers which are not typhoid fever we distinguish:

1. The ordinary moderate rises of temperature, only lasting for a few hours, occurring within three weeks after the end of a typhoid fever. These short fevers would not be recognized at all unless the temperature was systematically taken, for they are not attended with any symptoms and do no harm. The only important thing about them is to understand that they are not of importance.

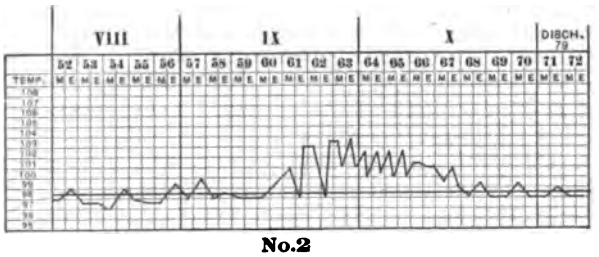
2. The post-typhoid fevers which are of real importance, and last for one or more weeks, but yet do not make the patient very ill and are not fatal.

In 1898 Dr. Da Costa published a clinical lecture on "Post-typhoid Fever," in which he gave a good description of these fevers and recognized clearly that in order to bring them to an end it is necessary not only to give the patients solid food, but to get them out of bed.

If one looks for this form of fever it is found to occur quite frequently. I have seen it after typhoid fevers of two, three, or four weeks' duration. The rise of temperature is continuous with the typhoid temperature, or there may be an interval of several days of normal temperature and then the post-typhoid fever begins.



No. 2

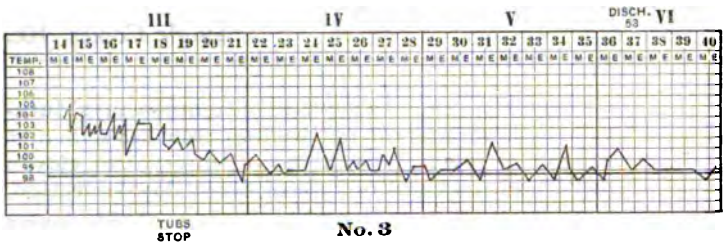


No. 2

The morning temperatures run pretty near the normal. The afternoon temperatures run from 100° to 103°, with occasional jumps to 105° or 107°. With the very high temperatures there may be chills.

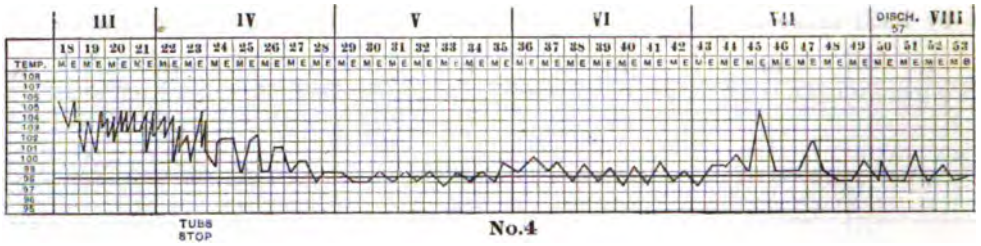
*A paper read at the meeting of the Association of American Physicians, May 12, 1903.

With this fever there is no delirium or sleeplessness, the tongue is moist and clean, there is no eruption, no tympanitis, no diarrhœa. The patients are hungry. If they are not fed they may have rather alarming attacks of heart failure. As long as the patients are kept in bed and on a fluid diet there is no particular limit to the duration of the fever, but yet in the end they get well.



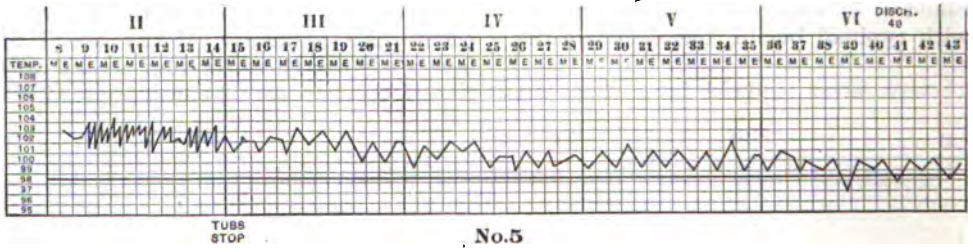
No. 3

Chart No. 3 is of the three weeks typhoid. After the typhoid there was an intermission of two days. After that the afternoon temperature ran from 100° to 103° until the thirty-eighth day. The patient was fed on the twenty-third day, taken out of bed on the thirty-third day, and discharged on the fifty-third day. After the twenty-third day he gained steadily in strength and had no bad symptoms except the fever.



No.4

Chart No. 4 is of a four weeks typhoid, followed by an intermission of seven days, then the afternoon temperatures ran at 100°, with a rise to 105° on the forty-fifth day, of 102° on the forty-seventh day, and of 101° on the fifty-first day. The temperature fell to the normal on the fifty-third day, and the patient was discharged on the fifty-seventh day. He was fed on the twenty-eighth day, and taken out of bed on the thirty-fourth day. He gained flesh and strength steadily after the thirty-fourth day; on the fifty-second day the hæmoglobin was 94 per cent., the red cells 5,280,000.



No.5

Chart No. 5 is of a three weeks typhoid. There was no intermission, but a steady afternoon temperature of 101° until the forty-third day. The patient was fed on the twenty-second day, taken out of bed on the thirtieth day, and discharged on the forty-ninth day. On the thirty-fourth day he was feeling perfectly well and rapidly gaining flesh and strength. On the forty-first day the hæmoglobin was 70 per cent., the red cells 4,722,000.

Chart No. 6 is of a two weeks typhoid with a positive Widal reaction. There was an intermission of six days. Then, on the twenty-first day, the temperature ran up to 105°, on the twenty-second and twenty-third days to 107°. With these rises of temperature there were chills and sweating, with some prostration. There was no thrombosis of the veins. On the twenty-fourth day he was doing well, on the twenty-eighth day he was out of bed, and on the forty-sixth day he was discharged.

It is very interesting in these patients, if they are fed and taken out of bed, to see how they steadily gain flesh and strength in spite of the fever.

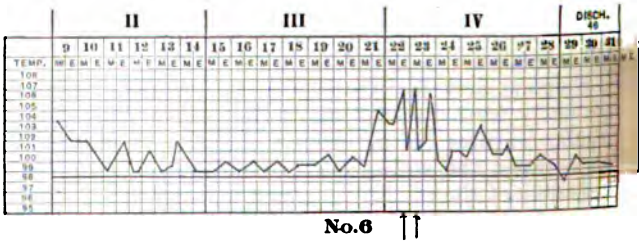
3. Much more important than these mild fevers are the severe and long continued post-typhoid fevers, which may terminate fatally. They occur regularly after well-marked and severe typhoid fevers which run their full four weeks' course. The septic fever is continuous with the typhoid fever. Sometimes it even overlaps it, so that both fevers seem to be going on together in the fourth or fifth week.

The morning temperatures run about 100°, and the afternoon temperatures about 103°. In many cases there are sudden jumps of temperature up to 105°, 106°, or 107°. These jumps occur in the course of the regular fever, or there are intervals of one or more days with nearly normal temperatures and then the sudden rise. With these sudden rises of temperature there are often chills.

It is noticeable that the septic temperature is not controlled by baths, as is the typhoid temperature, but runs up and down quite without reference to them.

The patients look septic and not in the typhoid state. The mind is often dull and apathetic, but they are not actively delirious. The tongue is dry, there may be nausea and vomiting, and yet there is some desire for food. There is a rapid loss of flesh and strength, as in ordinary sepsis, so that the condition may become alarming. In some of the cases there is thrombosis of one or both femoral veins. If the patients are insufficiently fed and kept in bed, they are very apt to die.

In the autopsies of the fatal cases which I have made, the intestinal lesions were healed and there seemed to be no cause of death but sepsis and starvation.



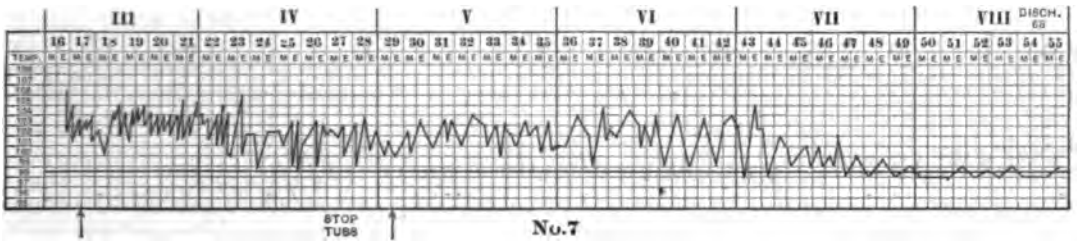
No.6

Some of the patients improve on food alone, but in most of them there is no real convalescence until they are taken out of bed. Then they gain flesh and strength, even while the fever continues.

It must be confessed that it requires a good deal of courage to take out of bed a patient who is ap-

parently dying. But I am fully convinced that the only way of saving the life of the bad cases is to feed them and take them out of bed.

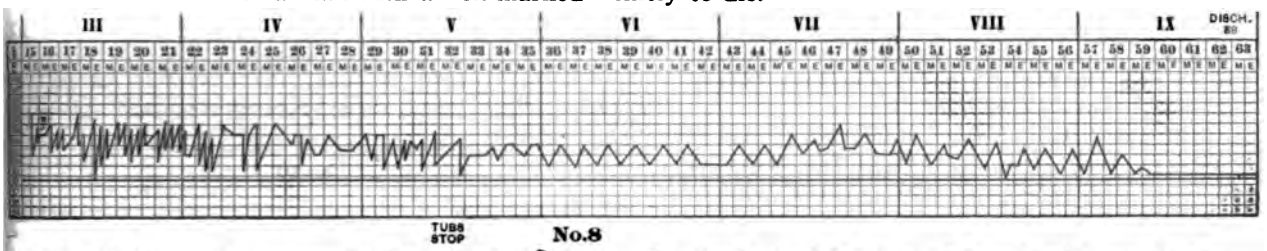
Chart No. 7 is that of a woman who had a pretty severe typhoid, favorably affected by tubbing,



No.7

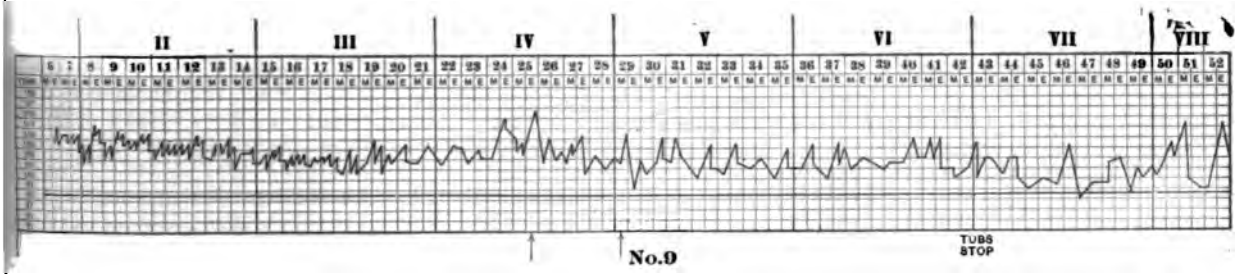
which ran its course in four weeks. On the twenty-ninth day she had a chill and then went on with the temperatures between 99° and 104° up to the forty-ninth day. She kept on in the septic condition, steadily getting worse and weaker until the forty-sixth day, then she was given solid food and after that the improvement was rapid.

Chart No. 8 is that of a man with a well-marked



No.8

typhoid which ran its course in four weeks. He was hungry on the twenty-sixth day. After this he ran along with temperature between 100° and 103° until the fifty-ninth day, but yet he was not so very sick. He was fed on the fortieth day, and taken out of bed on the forty-sixth day. Between the fiftieth and the seventy-eighth days he gained twenty pounds in weight.



No.9

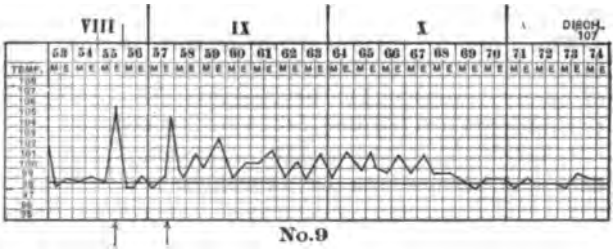
Chart No. 9 is that of a man who had a severe typhoid until the eighteenth day, when he was evidently less poisoned. On the twenty-fifth day he had a chill, the temperature ran up to 107°, and he looked septic. There was no thrombosis of the veins, the white blood cells were 6,900. Apparently the septic poison was overlapping the typhoid. He also had nausea and vomiting. He went on after this with irregular afternoon temperatures, often up to 104°, not at all controlled by tubbing, until the forty-third day, when the tubs were stopped. They had been of absolutely no use after the twenty-first day.

On the forty-fifth day he was fed. On the forty-seventh day, although he was so ill and weak it seemed doubtful if he would recover, he was taken out of bed. After this the temperatures were very irregular, running up to 106° and down to normal. There was no real improvement until the fifty-first day. After that he improved steadily, although there was thrombosis of the left femoral vein on the fifty-ninth day and of the right femoral vein on the sixtieth day. There was no more fever after the sixty-eighth day. He gained thirty pounds in weight between the sixty-ninth and the one hundred and fifth day.

Chart No. 10. This is perhaps the most interesting case of the series. The man had a pretty severe typhoid, but began to improve on the twenty-fifth day and was fed on the twenty-sixth day. He continued to improve, although the temperatures were up to 104° in the afternoon, until the thirty-third day. Then he had a chill, the temperature ran up to 106°, there was thrombosis of the left femoral vein, and he looked distinctly septic. After this he failed steadily, lost flesh and strength and seemed likely to die.

On the forty-third day, although with much misgiving, for it seemed like handling a dying man, I got him out of bed. The chart shows that during the following week the temperature did not go over 101°, and his general improvement was most satisfactory. After this he got steadily better, although he had irregular rises of temperature and a complicating orchitis on the seventy-sixth day. He was discharged on the eighty-third day.

Chart No. 11. This man went on with an ordinary typhoid until the third week, when the temperature began to rise. In the fourth week he had high septic temperatures with chills, and on the twenty-fifth day thrombosis of the left femoral vein. On the thirty-eighth day he had thrombosis of the right

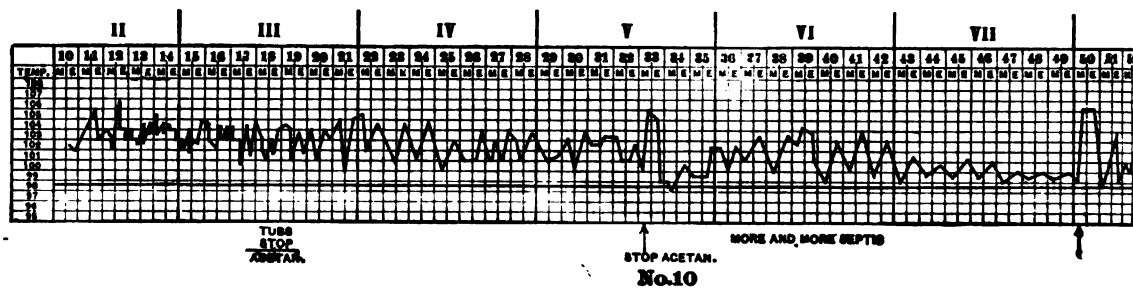


No.9

femoral vein. He went on with irregular septic temperatures until the fifty-ninth day, but yet his general condition improved after the thirty-ninth day. He was fed on the thirty-ninth day, taken out of bed on the forty-third day, and discharged on the seventy-eighth day.

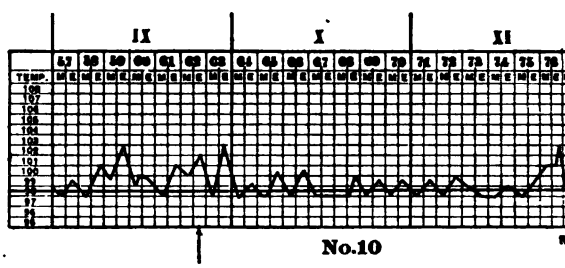
Chart No. 12. This man had a typhoid fever last-

ing for four weeks. Then there was an intermission of three days; after that came a true relapse which lasted for ten days. During the relapse he began to become septic and developed thrombosis of the



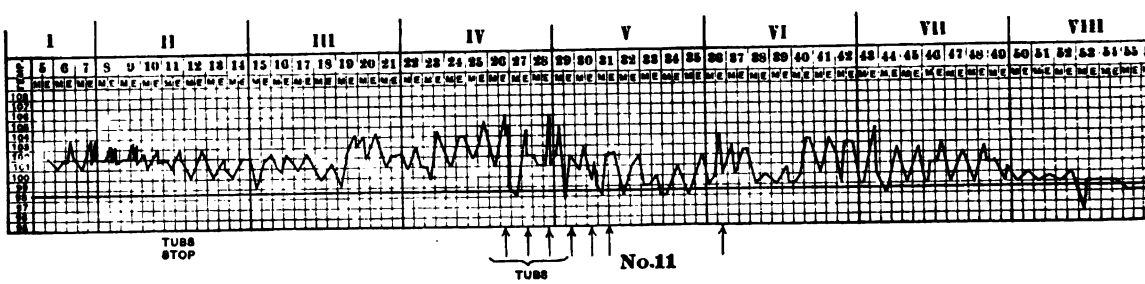
No.10

right femoral vein on the thirty-eighth day. In the seventh, eighth, and ninth weeks the rises of temperature were curious, with intervals of one, two, three, and four days. There were no malarial organisms in the blood. He was fed on the thirty-seventh day, taken out of bed on the fifty-second day and discharged on the seventy-fourth day.

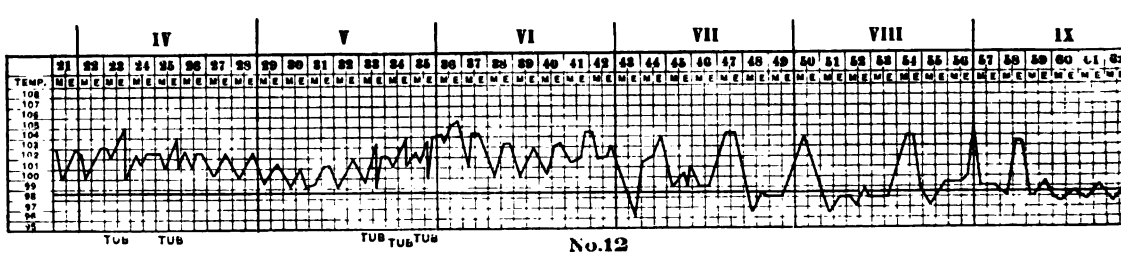


No.10

The impression I have received from the tudy of such cases is that at the end of a syphoid fever there may come in a new infec-



No.11



No.12

tion which resembles a streptococcus infection. This infection may be mild or severe. With care I think it can usually be distinguished from the typhoid infection.

The point of practical importance is that this infection calls for a different management from that of typhoid fever. The best results are obtained if the patients are fed and taken out of bed.

It is to be noticed that this post-typhoid infection occurs in private practice as well as in hospitals.

In the charts the arrows at the bottom indicate chills.

The charts as seen here are reduced from large charts prepared for me by Dr. Rolfe Floyd.

---

**Toilet of the Peritoneum in Gunshot Wounds of the Stomach and Intestines** —George Tully Vaughan considers that in cases of wounds without peritonitis and with no escape of visceral contents, neither irrigation nor drainage of the peritoneal cavity is necessary. When there is extravasation of visceral contents, thorough cl the peritoneal cavity is absolutely necessary best accomplished by sponging, followed by with large quantities of salt solution, removing tines from the cavity if necessary and the cond patient will permit it. Unless satisfied that th is perfect, drainage should be used through the the female this is done by opening from the the pouch of Douglas, and in the male by t retrovesical peritoneal pouch by an opening in ineum between the rectum and the urethra. hemorrhage with the formation of blood clots, been imperfect hæmostasis, irrigation is indicat general drainage. In cases of local peritoniti involved should be drained. Irrigation must b caution if at all, lest other parts be infected by ing up of slight adhesions and the escape of th fluid, perhaps conveying the germs to distant p abdominal cavity. In circumscribed abscess toneal cavity, if the discharge continues un long the abscess may be washed out with bichl tion 1 to 5,000. In general peritonitis t should be given a chance for life by thorough and efficient drainage.—*Annals of Gynæ Pediatry.*

# THE JOINT COMPLICATIONS OF ACUTE PYOGENIC OSTEOMYELITIS, WITH ESPECIAL REFERENCE TO THE TREATMENT OF THE PURULENT FORMS OF ARTHRITIS.*

By A. A. BERG, M.D.,
NEW YORK.
ADJUNCT SURGEON TO MT. SINAI HOSPITAL.

The old adage, "an ounce of prevention is worth more than a pound of cure" holds particularly good, for the serious forms of arthritis that complicate acute pyogenic osteomyelitis; for a joint that has become the seat of a severe inflammation will probably suffer a permanent impairment in its function. Prevention lies entirely in the attendant's ability to make an early diagnosis of the primary bone infection, and in his rapidly carrying out the treatment such acute bone disease demands.

It is well to remember, for diagnostic purposes, that, like other serous membranes, the synovial is never inflamed idiopathically. Though apparent instances do from time to time occur, these will become less frequent as our knowledge of pathology and bacteriology increases. It may be stated as an axiom, though, as just said, not at present without apparent exception, "that an acute arthritis is always a secondary manifestation;" it behooves the attendant therefore to ascertain the primary exciting factor. It is unfortunate that our knowledge of the etiology and pathogenesis of a very large class of joint lesions, viz., the rheumatic and gouty, is so imperfect as to permit of classification with them of many joint inflammations that bear them some clinical resemblance, but whose etiology and pathogenesis are of an entirely different nature. Just because of the present haziness of the exciting causes of rheumatic and gouty joint lesions, a given case should never be put in their class until every other etiological factor in its pathogenesis has been carefully excluded. Early, accurate diagnosis of acute bone infection with rapid opening and drainage of the medullary cavity will save many a joint from severe inflammation and permanently impaired function.

*Pathology:*—In the consideration of the acute arthritides accompanying acute pyogenic osteomyelitis it is first of all very important to distinguish between two distinct types: the one, sympathetic or pseudoarthritis; the other, true inflammatory arthritis. The former accompany the very early stages of the bone infection. In their pathogenesis they are similar to the sympathetic reactions of the tissue surrounding an infected focus, in the cellular planes, or to the local serous effusion in the peritoneal cavity, around an intensely inflamed appendix. They are due to the congestion and exudation from the lympathics and capillaries in the neighborhood of an inflammatory focus, and as a rule the degree of the congestion and exudation is in proportion to the severity of the primary lesion. Such sympathetic joint manifestations are often the first and only physical signs of a very virulent acute pyogenic osteomyelitis; this accounts for the fact that such cases are frequently looked upon as acute articular rheumatism.

The true joint inflammations are due to a bacterial invasion of the affected part, either directly from the neighboring bone, or indirectly through the medium of the blood; the latter, representing metastatic deposits, are frequently multiple, whereas the former are single. The sympathetic or pseudo-arthritides add in no way to the severity of the septic symptoms arising from the primary bone infection, and tend to subside spontaneously when the primary infection has been leaving no permanent functional impairment evacuated and drained. The true bacterial arthritis, however, adds materially to the patient's toxæmia, itself requires proper surgical interference, and is very apt to leave the joint seriously impaired in integrity and function. Such bacterial infection of joints may occur very early in the course of the primary bone disease, or several weeks after its onset.

*Types of Joint Lesions.*—It is to be noted that the joint is rarely involved alone; there is usually a coincident inflammation of the periarticular structures. This is present in the mildest and severest grades of arthritis and in the sympathetic manifestations, and is not in proportion to the severity or type of the joint lesion, but is often much more intense. It is of much importance from a differential diagnostic standpoint; thus the acute rheumatic and gouty inflammations, and the various types of arthritis secondary to pyæmia or septicæmia are at first confined to the serous membrane of the joint cavity, with little or no periarthritis.

The early stages of acute bone infection are usually associated with the sympathetic or pseudo-arthritis. This manifests itself by serous, or serofibrinous, effusion into the periarticular tissues, and synovial cavity. Such effusion does not contain the virulent bacteria that are present in the bone; it is to be again noted that such sympathetic or pseudo-arthritides are not true inflammatory lesions, but merely represent a passive exudation into the joint cavity and periarticular structures.

Serous, serofibrinous, and purulent exudates the result of true inflammation of the joint and periarticular tissues, accompany the more advanced stages of bone infection. Such exudates usually contain the same virulent bacteria as are found in the primary focus. At times the exudate is of ropy consistency, and cloudy, from the presence of a few pus cells and fibrin flocculi, the catarrhal exudate of von Volkman. In such exudates also the bacteria are to be found. It is but recently that such catarrhal synovitis has been proved to result from acute osteomyelitis. It is very probable that the bacteria in these cases causing the primary bone lesion are of diminished virulency, and hence give rise to a much less intense infection of the bone and joint.

*Symptomatology.*—With referenee to the symptomatology to which such joint lesions give rise, I desire to dwell especially upon this most important point, viz., that acute pyogenic diseases of bones in the neighborhood of joints frequently give their first manifestations by an exudate in the respective joint. This fact is often overlooked, the joint inflammation being attributed to rheumatic infection. The writer wishes to emphasize that no acute joint lesion should be looked upon as rheumatic or gouty until an acute inflammation of the bones entering into the formation of the joint has been positively excluded. Especially in children is this most important, for in them rheumatism is relatively infrequent while acute osteomyelitis is quite often met with.

The true forms of arthritis intensify the symptoms of sepsis produced by the primary focus of infection, and in addition give the characteristic physical signs of exudate into the joint and periarticular tissues. It is also important to note that a continuance of the constitutional symptoms after satisfactory evacuation and drainage of the infected

*Read before the Orthopedic Section of the New York Academy of Medicine.

medullary canal is frequently due to the co-existing joint inflammation.

*Treatment.*—The treatment of these acute joint inflammations demands, on the surgeon's part, his keenest judgment as to whether it should be expectant with local applications, and immobilization, or whether operative interference should be undertaken. If the latter, when is the best time to operate, what should be the extent of the attack and what type of operation should be performed? In forming the decision, it should be constantly borne in mind that these cases are likely to be extremely septic ones, and that delay in the proper and timely treatment may result most seriously to the limb and life of the patient.

As regards the time in which it is best to operate the cases may be roughly divided into two classes: those that develop coincidently and hand in hand with an adjacent bone infection, and those that develop later in the course of the osteomyelitis either from extension of the infection into the joint or as metastatic pyæmic manifestations. The writer is led to make this classification for the following reason: In the first class of cases we are called upon to treat what is apparently a combined infection of the bone and joint, and the question must arise, should the operative attack be limited to the infected medulla, or should it also be directed at the same sitting against the complicating joint lesion. This problem will scarcely arise in the second class of cases as the joint inflammation is a later manifestation of the disease, and would naturally demand such treatment as is usually carried out in joint lesions of a similar character due to other causes.

The practice of the writer, both as regards the time for interference and the character of such operation, is as follows:

In every case of acute pyogenic osteomyelitis a blood culture is taken at the time of the primary operation. This is of importance not only prognostically but also as an aid to a complete and clear understanding of the complications, that may develop in the further progress of the disease. When there is only a periarticular effusion, no interference is practised at the time of the primary operation. After evacuation and drainage of the infected medullary cavity of the bone, the joint is immobilized in a fenestrated starch and veneer dressing, and an ice-bag applied to the affected joint. When the joint cavity is distended, by an exudate, an exploratory puncture is made preliminary to attacking the bone itself. Such exploratory aspiration should be made preliminary to the opening of the infected marrow canal, otherwise the joint may be infected through the medium of our septic instruments or by a puncture in an infected operative field. Should the exudate be serous, or serofibrinous, or even turbid, seropurulent fluid, no interference with the joint is made at that time, simple immobilization with ice applications being carried out. For it must be remembered that in many of the cases such an exudate is a manifestation of sympathetic or pseudo-arthritis, and that in these instances it will subside spontaneously with the trephining and drainage of the infected medulla of the bone. The writer has within the past year treated three cases in which there was, complicating to an acute epiphysitis of the lower femoral end, a marked periarticular and articular effusion into the knee, of serum in two cases, and seropurulent fluid in another. Spontaneous resorption of the exudate followed in all three cases, after trephining and drainage of the epiphyseal end of the bone. The fluid yielded by aspiration is always examined bacteriologically both on cover slips and by culture. The presence of bacteria in the exudate does not necessarily demand immediate interference with the joint, for the writer has several times seen spontaneous absorption of such exudates after drainage of the primary focus.

Should the arthritis not show evidences of subsidence after proper drainage of the bone, and the temperature and pulse rate continue elevated, with no other cause, *e.g.* a septicæmia or pyæmia, for the persistence of these symptoms, a second exploratory aspiration is made. If its character has remained unchanged, a wide trocar and cannula is introduced on either side of the joint, the exudate evacuated, and the joint cavity thoroughly washed out with 5 per cent. carbolic acid, followed by normal saline solution. A compressive immobilizing dressing is applied. Such a procedure is usually followed by recovery of the joint, but should there be a reaccumulation of the exudate the irrigation may be repeated. In one of the writer's cases this had to be done twice before the inflammation subsided. Occasionally, in spite of such aseptic evacuation and irrigation, the inflammation does not subside, but goes on to true suppuration of the joint.

Should the complicating arthritis be of a suppurative type, the indication is to secure free and perfect drainage. The method by which this is accomplished varies in the mild and severe forms of suppuration. In the former there is, beside the purulent exudate into the joint and periarticular tissues, very little tendency to destruction of the synovial membrane, cartilages, or ligaments, and the septic symptoms arising from such a pyarthrosis are not of a severe grade. In the severe forms of suppuration the purulent exudate is attended with more or less extensive destruction of the component joint parts, and the septic symptoms are very intense. So radically different in their character are these two varieties of suppurative arthritis that their treatment must naturally be very different. In the first class the evacuation of the pus with the proper provision to prevent its reaccumulation will suffice to put an end to the suppurative process; whereas in the second group of cases the inflammation is so virulent, and the destructive process is so rapid, that the mere evacuation of the purulent exudate does not meet all requirements. To limit the further extension of the inflammation and destruction we must make such provision that every part of the joint will be laid freely open, and drained, otherwise the advancing destruction and the continued resorption of the septic products, arising from imperfect drainage, tax the patient's strength and vitality, and compel the surgeon to amputate the affected part in order to save the life of the patient.

The writer does not hesitate to say that not sufficient stress has heretofore been laid on the different types of suppurative arthritis; they have all been classed under one heading, and their treatment has been considered in common, whereas in reality there are two distinct varieties; in the one a purulent exudate is the chief lesion, there being comparatively little change in the components of the joint; in the other the purulent exudate is secondary in importance to the destructive imflammation of the synovial membrane, cartilages and ligaments.* In the first type the function and integrity of the joint may

*In this respect the joints follow the same rule as do other parts lined by serous membrane, *e.g.* pleura and peritoneum. We have called attention in a previous communication on "The Peritoneum and the Exudative Types of Peritonitis" that it is not the character of the exudate that decides the virulency of the inflammation, but the extent of the morbid changes of the peritoneum itself.

be completely restored after the subsidence of the inflammation. In the latter it is evident from the very outset that both function and integrity cannot be preserved, and that if we would save the limb and life of the patient something far more radical than the evacuation of the exudate and drainage by tube or gauze must be done.

For the milder grades of suppurative arthritis the time-honored methods of single or multiple incision of the joint, evacuation of the exudate and drainage by tube or gauze yields very good results, and, as stated elsewhere, such joints may be completely restored to function by these simple methods. Whether constant irrigation of saline solution should be employed in conjunction with drainage depends entirely on the consistency of the exudate. If it is thin and watery and easily escapes through the tubes such irrigation is unnecessary; if it is thick and ropy and is retained, continued irrigation will materially aid its free escape. The affected part is immobilized.

For the severe types of suppurative arthritis affecting the knee-joint, Drs. Mayo of Rochester, Minn.. advised a transverse anterior incision, through the patella into the joint, with partial dislocation of the femur and tibia by extreme flexion and dry packing of the synovial cavity of the joint. This permits of easy access to every crevice, enables the surgeon to remove all the destroyed tissues, to incise freely the œdematous and congested soft parts, and absolutely does away with retention within the joint. It is, of course, evident that such a procedure forbids the restoration of the function and integrity of the affected joint, but, as I have stated above, these cannot be preserved by any form of treatment. Of four cases of knee-joint suppuration of very intense type treated by the writer after this fashion, three healed with fibrous ankylosis, and in one the destruction could not be limited by even this incisive procedure,* final resort being had to amputation in order to save life. So impressed has the writer been by the good results of this suggestion of the Drs. Mayo that he proposes to extend this procedure to the other large joints, but especially the elbow, ankle, and wrist. The hip and shoulder-joints are so thickly covered by soft parts that the procedure is more difficult.

In the case of the elbow a semi-lunar posterior incision from side to side, convexity downward, the level of the convexity at the base of the olecranon, should be made, avoiding the ulnar nerve at the inner side. The olecranon is then divided by chisel or saw at its base, either removed or reflected upward with the triceps muscle, the capsule transversely incised and the joint strongly flexed, thus dislocating the bones backward. Dry gauze tamponade and dressing in flexion.

In the ankle a longitudinal lateral incision over either aspect should be made, the corresponding malleolus transversely divided at its base, removed, and the joint forcibly flexed to the fibular or tibial side, thus dislocating the joint inward or outward; dry aseptic gauze packing and dressing, and immobilization in such laterally flexed position.

In the wrist, a longitudinal dorsal incision, over the lower end of the radius with strong retraction of the tendons to either side, will permit of backward dislocation of the lower end of the radius and dry aseptic gauze packing of the joint, dressing and immobilization in this position.

The after-treatment is very simple.

The first dressing, which is made very copious, is left *in situ* for six or seven days, unless a continuance of the temperature necessitates an earlier change. The outer dressings may be renewed whenever they become saturated with the discharges. At the end of a week, granulations appear; the cartilage covered surfaces at times have a cloudy aspect. After thorough cleansing and irrigation of the entire joint, it is again packed with dry aseptic gauze and dressed in the same partially dislocated position. It is advisable to make the earlier change of the deep packings under full anæsthesia. When sufficient granulations have appeared to warrant the assumption that the suppurative process is at an end (a condition that usually takes from ten to fourteen days) the bones are reduced into their normal position, and the soft parts united by secondary suture; proper provision being made for drainage. The joint is kept immobilized until union of the soft parts has occurred. Fibrous ankylosis of the joint is the rule, though its degree varies. In two of the writer's cases, a range of 5° of motion was possible. Passive motion should not be resorted to before complete union of the soft parts has taken place.

The writer feels assured that results equally satisfactory to those obtained in suppurative gonitis will follow the application of the Mayo operation in similar suppurative conditions of the other joints.

The after-treatment of the other forms of arthritis consists in immobilization of the affected joint until the acute inflammation subsides; passive motion is then cautiously commenced. Forcible passive motion is to be deprecated; for the rupture in this way of recent vascular adhesions causes hemorrhage into the joint, which in turn is followed by other firmer adventitious bands. For the periarthritis a Priesnitz cold pack, combined with douches and massage, are employed with satisfactory results.

Late results of these arthritides:—The pseudo-arthritis and periarthritis leave no ultimate impairment of the joint function, although a thickening of the joint structures may persist for some time. Likewise the serous, serofibrinous, and catarrhal, types of arthritis. Prolonged drainage of the joint for pyarthrosis, is usually followed by fibrous ankylosis. The degree and permanency of this varies, and depends mainly upon the extent of destruction of the soft and bony joint structures. The writer has had cases in which the joint function was completely restored, whereas in others dense fibrous ankylosis supervened.

Temporary partial dislocation of the joint with dry aseptic gauze packing, is always followed by ankylosis. Much, however, can be expected from plastic operations, *e.g.* the insertion of magnesium plates or flaps of fascia between the articular surfaces, to restore the function of the joint.

**Pyelitis as a Cause of Intermittent Pyrexia in Children.**—W. Cecil Bosanquet describes the cases of this affection. The frequency with which it occurs, he says, is difficult to estimate, as it is a condition which can easily be overlooked. Morse considers that it is not at all uncommon. It does not appear to be dangerous to life, in spite of the severity of the symptoms to which it gives rise. It must not be supposed that every rise of the thermometer is to be attributed to this cause, as an attack of indigestion after any indiscretion in diet may often be accompanied by fever. Still there remains a number of cases in which the condition is more serious, the feverish attacks being accompanied by pronounced symptoms of illness. It is important to make a careful examination of the urine in obscure cases of pyrexia, especially when it is of a recurrent type.—*The Edinburgh Medical Journal.*

## ANCIENT JIBES AT THE DOCTORS.*

By JONATHAN WRIGHT, M.D.
BROOKLYN N. Y.

The title of this paper has been chosen advisedly. The jibes against the doctors *are* ancient. A philosopher has said there are really fundamentally only a half dozen or so really good jokes of any kind, and these have come down to us from prehistoric times. Long before I thought of studying medicine or of anything else so serious—in my "salad days"—Molière was my delight. A half hour with "Les Femmes Savantes" was worth much more than a longer time with the other kind. To "Le Bourgeois Gentilhomme" and "L'Avare" I owed, in those days, many a midnight chuckle and many a brightening of a gloomy morning. After I had reluctantly begun the serious business of life, after many a prolonged seance with Niemayer's Practice and many a weary sojourn with the Wochenschrifts, "Le Medecin Malgre Lui" was the solace of a bruised heart and an aching head. After many a perplexing hunt through the tortuous mazes of a female patient's nasal passages for the origin of a reflex neurosis, I turned with huge delight and a secret joy to "Le Malade Imaginaire." Molière for me was the most enjoyable and original of jokers. In fact, there is hardly any class of human society to-day whose foibles and faults were not laughed at two centuries ago by his audiences. There were, however, two kinds of people he did not make fun of; one was the nobility, and one was we specialists. The first because he did not dare, and the other only because we were not alive then. What fun he would have gotten out of us!

After one has drifted in one's reading into Rabelais, Molière's reputation for originality somewhat wanes. Petrarch's Latin works must convince one that Molière's genius lay rather in the adaptation of the former's more profound and bitter diatribes, but the inimitable drollery of his characters who cracked Petrarch's jokes anew are irresistible. Petrarch drew his inspiration not only for the learning which inaugurated the Renaissance, but for that which adorned his invectives against the doctors, from an earlier civilization, and when one turns to Pliny, the elder, and old Cato, the same time-worn satires start from their pages. Roman literature derives all of its virtues and much of its substance from the Greek, and hence it is but a step to Aristophanes and Plato, and now again the somewhat threadbare jibes are found. Some recent work has led me into still more recondite and musty nooks of medical lore, and I have read the Hindu Susruta and the Egyptian Papyrus Ebers and looked through the Zend Avesta. I am sure if there were jokers in those dim twilight days of history, and there surely were, they might have found plenty of material in the profundity of Charaka, the sage, and the hieroglyphs on the tombs in the Delta of the Nile.

Wit is only enjoyable, however, when it flashes occasionally from the printed page or ripples spontaneously from smiling lips. When it is bound together in one disgusting mess, as in Witkowski's book "Le Mal qu'on dit des Medecins," or drones wearisomely through Petrarch's labored Latin periods in his interminable Invectives against the medieval doctors of Avignon, it palls on the taste, and like highly spiced food with every course weakens instead of strengthens digestion. But to see ourselves occasionally as others see us, to join in the joke at our own foibles as we toil along in the earnest work of life is a salutary occupation for us all. Let us laugh then, and keep resentment from our hearts. Renan, in one of his sublime passages, says in his life of Christ: "Jesus possessed in the highest degree that quality which we regard as the essential characteristic of a distinguished personage. I mean the power of smiling over his work, of being superior to it, of not allowing himself to be mastered by it." We have every reason to keep ourselves in this philosophic state of mind, for almost every wit that has put pen to paper has had a shy at us. We have been scored by Cato the censor and Petrarch the humorist, by Montaigne the critic and Molière the buffoon.

As I look along the goodly array of glassware on this table, I am reminded that doctors have always been fond of dinners. I suppose they are a sort of escape valve, a relief to the tension engendered by the miseries of life of which we know so much. At any rate notices of the convivialities of our brotherhood may be found on many an ancient page. I quote from a letter of a medical contemporary of Molière.

"Yesterday I gave my dinner. . . . Thirty-six of my colleagues had a fine feast. I never saw so much laughing nor so much drinking among serious and elderly people." We may believe that the old Salernitans derived from experience the verse:

*"Ut sis nocte levis,*
*Sit tibi cenis brevis."*

Let us remember that a few years of our experience as doctors accustom us to many, if not to all of the real tragedies of life. This hardening process is a necessity. No sentient human being could long endure the agitation with which the medical novice views his first operation or undertakes his first responsibility, or looks first into the depths of human mystery and degradation. Happily the emotions are soon blunted, and this is an involuntary, almost an insensible, psychical change.

No such automatic relief, however, comes to the toiling mental machinery of the conscientious worker in medical science. In a few years he becomes engulfed in the problems of his profession. His mind becomes warped and twisted by the unrelenting strain. Phantasms crowd in upon him. He sees things not as they are, but as they loom up before him through the mist of his environment. He is in danger of becoming pedantic and unsympathetic. Let him occasionally turn his back on medicine and pull his mind out of its ruts. His interest in art or music, or mechanics, or literature will make him better and stronger, and he will move in surer tread when he steps into the ranks again. Nothing will do the medical man so much good as to read the jokes and jibes of his critics.

The best jokes, as I have said, are the old ones. From day to day, from year to year, from century to century, even from one civilization to another, they are scattered through literature and the daily intercourse of man. Even old Aesop, the poor old slave, brings physicians in for their share of satire in his fables. Even the fabled god Æsculapius and the more real Hippocrates, our revered parent, did not escape the taunts and the execrations of Aristophanes and the mocking wits of Athens. Why should we? Aristophanes, Boccacio, Molière and Cervantes, Dickens and Mark Twain, and our weekly comic papers make us laugh anew over the same old story, told in different accents and in different syntax.

You remember how Rip Van Winkle, in the play, looks at Sir Hendricks' mutes on the mountain and wonders vaguely if there are any girls in the family, and with thoughts of Katrine, says: "What wives

*This paper is largely made up of notes read several years ago at a dinner of the Brooklyn Medical Club, and more recently of these and others read at a dinner of the Hospital Graduates Club of New York.

they would make!" We recall immediately the jokes that ran through Athens two thousand years ago about Xanthippe and Socrates. Rabelais puts the story in the mouth of Panurge, who tells of a good man who had married a mute wife. He wanted her to speak, and he concluded she must be tongue-tied (like our little patients in the dispensaries); so he induces a surgeon to operate on her. The success of the treatment transcended by far any with which we are familiar to-day, and so overshot the mark aimed at by the solicitous husband that he soon returned to the doctor and prayed him for relief from his wife's volubility. The physician very sagely remarked that it was one thing to start a woman to talk and quite another to stop her. In short the only relief he could suggest was to make the husband deaf. To this the latter acceded, and the medical man was again successful, and thereupon demanded his pay. It was before the days of bills by post, and the patient was entirely too deaf to understand such a demand as that. This part of the story we are also in a position to appreciate. This physician of the middle ages concluded that this kind of doctoring would not do at all, so he proceeded to fill his patient up with all sorts of drugs to restore his hearing. Whether he took out his ossicles or not the tale does not say, but at any rate he succeeded in driving him crazy, whereupon the much-suffering lunatic and his enraged and voluble helpmate fell upon the doctor with clubs and beat him into insensibility.

It is certain that Molière must have had this little anecdote of Rabelais in mind when he wrote one of the scenes in that wonderful comedy "Le Medecin Malgre Lui"—a comedy which has been the source of inextinguishable laughter for more than two hundred years. It is the scene wherein the pretended doctor is called upon to restore speech to the young woman who is about to be married, and to the anxious entreaty of the distressed father who says the bridegroom awaits the cure of her infirmity, he exclaims, "What a fool he is! I wish to heaven my wife were afflicted with the malady. I would take good care not to have her cured."

In hinting at the wide extent of a doctor's practice, the following has a strangely familiar sound to-day. It is a conversation between two doctors at a consultation—M. Desfondres and M. Tomes. Says the former: "Paris is a wonderfully big place, and a man has to make long trips when his practice is a little extensive." "I have an excellent mule for that," says M. Tomes; "it is astonishing what a drive I give him every day." M. Desfondres interrupts: "I have a wonderful horse; he is a tireless animal." M. Tomes continues: "Do you know how far my mule has been to-day? First I went clear over opposite the arsenal—from the arsenal to the end of the Fauburg St. Germain, from the Fauburg St. Germain to the end of the Marais, from the end of the Marais to the Port St. Honore, from the Port St. Honore to the Fauburg St. Jacques, from the Fauburg St. Jacques to the Port de Richelieu, from the Port de Richelieu here, and from here I ought to go to the Place Royale." M. Desfondres is not discouraged, but says, "My horse has done all that to-day, and in addition I have been to Reuil to see a patient." Paris no longer has a monopoly of such tireless animals.

After some little experience in medical practice into which he had suddenly been thrust against his will the pretended doctor in "Medecin Malgre Lui" expresses his admiration for his calling: "I find it the best of all trades, for whether it is well done or badly done, it is always paid alike. Bad work is never thrown back on our hands, and we cut away at the stuff upon which we work just as we please. Now, a shoemaker in making shoes can't spoil a piece of leather without paying for it, but at this business we can spoil a man and it doesn't cost us a sou. The blunders are not our fault, but we blame the patient, who dies. Now the beauty of this profession is that among dead people there is the greatest amount of charity possible, and of discretion, for the corpse who complains of his physician has never yet been seen." Unfortunately, since the days of Dr. Sganarelle, autopsies have become uncomfortably frequent, and the corpse does sometimes complain of his physician. This is one of the oldest and most time-worn of jibes against the doctors. It runs straight back through Petrarch to Pliny, crosses over into Greece, and there we find Plato even putting it in the mouth of Socrates, who compliments an unsuccessful painter who had abandoned his art for medicine. He congratulates him because formerly he had exposed his shortcomings to the public gaze while now five or six feet of earth hide them.

Petrarch elaborates the jibe in phrases which Molière seems to have copied almost word for word. Petrarch declares that "the medical trade has the rarest of prerogatives, inasmuch as it is never punished for its mistakes; the earth hides the doctor's sins, as Socrates long ago said, and medicine is the safest of all callings, for in every other, the slightest slip of which the doer is guilty brings him to shame; indeed for a death for which every one else is punished with loss of life, he is rewarded. This unholy privilege to act as the lord of life and death is not possessed by king or kaiser. What wonder is it, then, that the doctors out of death carve their domain and their revenue." With this view of a doctor's responsibilities, it is not strange that we find old Henri di Mondeville, Petrarch's contemporary, counselling what now, with a more enlightened public, and perhaps with a profession less given to quackery, seems pernicious and cowardly shirking of duty, "Since surgical experiments and defective work is so perilous in the human body," said Hermondeville, "therefore I advise, mindful of the words of Albucasis—that we should not touch very dangerous diseases, of which we judge there will not be a praiseworthy end and a return to health—operating with foresight and wisdom, not beginning perilous operations at all until he is well provided with the means of escaping perils. Let him have nothing to do with desperate cases." Fortunately a saner view prevails among the laity of to-day, in spite of their appendicitis jokes, and we are no longer regarded as the "Lords of Life and Death."

Pliny, himself the most credulous of mortals, arraigned mankind for their credulity, but struck a theme of criticism which we may still appreciate in these days of sesquipedalian phraseology when he explained why it was that the Romans of his day preferred Greek physicians. He avers that among those unacquainted with a learned tongue there is no greater authority than that which dwells in those speaking Greek, and they pay little attention to what concerns their health if they are able to understand the language in which the precepts are couched. "Thus, by Hercules, it is the only one of the arts in which it happens that any one is believed who forthwith declares himself a doctor, although there lurks no greater peril than this in any lie. But let this pass, for exceedingly sweet is the power to indulge in hope for one's own well being. There is no law will remedy this mortal weakness."*

*I translate very liberally from Pliny, Lib. XXIX, Cap. 1, Sec. 7 (17–18). Ed. Sillig, 1853.

So far did this infatuation go that Pliny declared it was necessary for the senate to prevent by legislation the results of the fatuity of some sickly souls who thought nothing more conducive to their health than therapeutical agents sold at a high price. Later, in the Arabian Renaissance and in the Middle Ages, this formed the basis for the sale of precious stones as articles of the pharmacopœia. Petrarch, in rather more cutting language, elaborates the strictures of Pliny. "Under these circumstances," Petrarch continues, "it would appear incomprehensible that mankind is not repulsed by the tyranny which the doctors exert so mercilessly, but on the contrary are always running after them. For indeed with them it is as with God, concerning whom it is said in the Psalms, 'Although he slew them, yet trusted they Him.' It would be incomprehensible were it not a fact as to fools that their number is legion, and that it is quite impossible to find a rational explanation of their actions. The underlying cause of this, however, is as Pliny long ago showed, the boundless credulity, the misery, the thirsting love of life by man who frantically clings to every glimmer of hope, and soothing the anguish of his soul with treacherous supports, he forgets the most familiar of his own experiences. Supported by the trusting confidence of the weak and the sick, these physicians strut around in ostentatious pride, and by the very richness of their dress and their dazzling appearance impose on the vulgar. And when one looks on these men prancing along with their golden chains on their purple-bedecked steeds, there is nothing lacking in their outward appearance to distinguish them from the old Roman Triumphators; they resemble them also in their deeds; and although each one of them may not have killed his 50,000, which was once necessary for a triumph, yet a good part of it, and whatever deficiency there may be in the quantity they make up in the quality, since they kill not enemies but citizens, and like every conqueror in his armor, they carry their booty in their cloaks. There is indeed only this difference that it was forbidden to the old Triumphators to kill their fellow citizens, and the doctors do this not only freely and unpunished, but expect to be paid for it."

"Medical practice is only a trade founded on gain, and that is striven after with lying expedients. It is a trade which is concerned with all sorts of disgusting and unmentionable details."*

Thereupon Petrarch explains why it is classed among the low and degraded callings by men of his times, and is not to be compared with that of an honest peasant who labors for the support of life which the doctor jeopardizes.

This seems to us to-day all very fine writing—if it only had enough truth in it to save it from being ridiculous, and perhaps Petrarch realized even in his day that he had somewhat overshot the mark. Occasionally he modifies these caustic opinions, suggesting that perhaps in olden times medicine may have been useful, but that of his time was totally degenerate and depraved. It must have been very vile indeed to have excited the spleen of a courtier of the papal court of Avignon. Petrarch, though the herald of a culture which was to overthrow the dominant ecclesiasticism of his day, was as devout as his freedom from many of the grosser superstitions of his times allowed. The scourge of medicine, he was the champion of religion. We doctors boast, and we have a right to boast, in every oration of self-congratulation that by limiting and all but banishing from civilized nations the ravages of smallpox, cholera, and perhaps the most frightful of all, the plague, before which Petrarch and his priestly friends fled in abject fear, we have in the last hundred years vindicated medicine as the greatest of all blessings vouchsafed to mankind. It is, perhaps, stretching our self-laudation beyond the bounds historical truth allows, but we may almost claim to have thus saved as many lives and prevented as much human misery as in any similar span of time has been caused by the endeavors of the orthodox to spread a true religion.

Petrarch continues in a deprecatory way: "I am not blaming the art, but its devotees, and not all of these, but the shameless and the impudent. You have never heard me say anything against physic, but rather against the physicians." It is almost in these same words that Molière advanced his own excuses. "Certainly," says Petrarch, "Medicine itself should yield unto me its sincere thanks, had it only a voice, if by thus doing I lay bare the present infamy which extinguishes its ancient glory with new follies."

After a view of the stagnant pool of universal ignorance, lies and deceit which are depicted in what I have just quoted from the vain, sensitive, wrathful, intellectual potentate of the pre-renaissance, it is refreshing to get a whiff of honesty and frankness from the same source, all the better if the picture never lived in the flesh, but was a concept which Petrarch himself engrafted on the feeble tree of ethics in his day. He reports the response of a practitioner to a reproach he made him (I suppose, for I quote second hand from Sprengel, not being able to find the passage in the medieval editions of Petrarch's Latin works, which alone contain his diatribes against the doctors and priests of the court of Avignon). The latter made an answer which, thank God, we still hear occasionally from members of our profession to-day who disdain falsehood in an age so self-satisfied with its own achievements and its own wisdom. Says Petrarch's honest doctor: "I fear, since God beholds the affairs of men, to commit the wickedness of criminally deceiving the credulous generality of men, to whom, were it known as it is to me, how limited is the aid a physician gives to the patient, or that he is powerless to do so at all, the pompous array of doctors would grow less and less. Truly they practise because their own wickedness and the credulity of their patients is so great; they take advantage of the simplicity of their fellowmen; they promise life and they destroy life, and out of this they carve their profit. I have never been tempted either to deceive or kill. I do not desire to grow richer by the misfortunes of any one. This is the reason which has turned me to other pursuits which I could practise more innocently." I have heard the same sentiments fall from the lips of many a man with a similar conception of honor and a similar temperament of skepticism 500 years later. Fortunately medicine now enfolds in its catholic embrace many a department in which a skeptical man's activities are not necessarily hampered by his conscience.

Doubtless in all this there is much that is morbid, and Petrarch's doctor, or perhaps it was Petrarch himself, with poetic license, not satisfied with nursing his own conscience, was too censorious about the consciences of his colleagues. Such things were very common in those days, and have not entirely disappeared in our own. Faust in his most somber mood was not guilty of this lack of charity, though to the skeptic the temptation is great, for none but the fool or the rascal arrogates to himself, though

*Unfortunately, as there is no modern edition of these invectives of Petrarch against the doctors, I have had to rely on the copious translated abstracts of Henschel, "Petrarca's Urtheil über die Medizin and die Aerzte seiner Zeit." Janus, Ersten Band, Ersten Heft. 1846.

the multitude frequently ascribes to him, the work of the Almighty.

In Goethe's immortal work we learn that Dr. Faustus bore a revered name among his fellow citizens not only for his learning, but because in his youth he, with his father, had worked heroically among those smitten with the plague, and, as the peasants thought, had saved many lives. They greeted him affectionately and respectfully when, in the first part, as an old man with his pupil, he walks among them on Easter Day. They remind him of their gratitude, but he has grown in years and wisdom and, as so often happens to us all, in skepticism. He exclaims, as every honest man must:

"To Him above bow down, my friends,
Who teaches help and succor sends."

He describes to the student Wagner the "magic medicine" he and his father used, and in the efficacy of which he had then believed:

"This was the medicine—the patients' woes soon ended,
And none demanded—who got well.
Thus we, our hellish boluses compounding,
Among these hills and vales surrounding,
Worse than the pestilence have passed.
Thousands were done to death from poison of my giving,
And I must hear by all the living,
The shameless murderers praised at last."

Each generation of doctors finds something at which to shudder in the practice of their predecessors. From contemporaneous accounts attacks upon the lower bowel seem to have been distressingly frequent in the therapeutics of the days of Molière, and the practice afforded him an opportunity for much merry-making, the satire in it being apparently not at all overdrawn.

In the *Revue Historique of Antwerp* there is a document bearing on the intimate life of the Cardinal Richelieu. (I am quoting second hand). Its title is "Items furnished for the personal use of the Monseigneur Cardinal Duc de Richelieu for the year 1635 by Perdreau, Apothecary to the said Monseigneur." This account is for that year only, and is for seventy-five clysters (or enemata) and twenty-seven boluses (suppositories) of Cassia without counting the laxative medicines and the bottles of cough syrup, the total amounting to the sum of 1,401 livres 14 sous, equivalent to about $350, which in those days was, of course, an enormous sum, and does credit to the commercial sagacity of the Parisian apothecary. One cannot help wondering, in these purer and holier times, how much the sly drugman had to give up. The valets of his Eminence must have done quite well.

Molière probably had Richelieu's drug bill or a similar one in mind when he wrote the scene in the Malade Imaginaire in which the patient gets an account of the various purgings and clysters he had received.

Argan, the hypocondriacal patient is seated at a table adding up his apothecaries' bill:

"Two and 3 are 5 and 5 are 10 and 10 are 20. Two and three are 5 . . ." Further he reads: "'Upon the 24th a gentle little enema, preliminary and soothing, in order to soften, moisten, and refresh Monsieur's entrails.' Now that always pleases me in Monsieur Fleurant, the apothecary, his expressions are always so civil. . . . Monsieur's entrails 30 sous—yes, but Monsieur Fleurant, being civil is not the only thing, being reasonable and not fleecing your patients is another—30 sous for an injection. Your customary charge is 20 sous, and 20 sous in apothecaries' weight means 10 sous. Moreover on the same day, a good purging enema made of a double catholicon rhubarb, honey of roses and other things, according to the prescription, for washing, sweeping, and cleaning Monsieur's lower bowel—30 sous—10 if you please. Further, on the same day in the evening, an hepatic julep—soporific and somnolent, made up to put Monsieur to sleep—35 sous—well I don't complain of that for it made me sleep well—10, 15, 16, 17 sous and 6 deniers. Further, on the 25th, a good purgative and strengthening medicine made of fresh cassia and Levantine senna and other things, according to the prescription of Monsieur Purgon, for expelling and evacuating the bile of Monsieur—4 livres. Hold on there, Monsieur Fleurant, Monsieur Purgon did not prescribe that I should be charged 4 livres for it—make it 3 livres, if you please. Further, on the same day, an anodyne and astringent draft for quieting Monsieur—30 sous. Further, on the 26th, a carminative enema for driving the wind out of monsieur—30 sous—10 sous, Monsieur Fleurant. Further, Monsieur's enema repeated in the evening as above—30 sous—Monsieur Fleurant—10 sous. Further, upon the 27th, a good dose made up to hasten the departure and chase away Monsieur's bad humors—3 livres. Further, on the 28th, a dose of milk whey clarified and sweetened to soften, mitigate, temper, and refresh the blood of Monsieur—20 sous." And so he goes on, and sums up the monthly bill thus: "So, for this month I have taken 1, 2, 3, 4, 5, 6, 7, 8 doses of medicine, and 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12 injections, and last month I took 12 doses and 20 injections. That's it; I am not surprised I have not been feeling so well this month as last. I will tell Monsieur Purgon, so that he will see that it doesn't occur again."

In the play of "Monsieur de Pourceaugnac" the doctor asks concerning his patient: "How many times has he been bled? Fifteen times, and he did not get well? No? Well, that is a sign the disease is not in his blood. We will purge him that many times to see if it is not in his humors; and if we don't succeed with anything we will send him away to the baths."

"Ah, now look at that," says the apothecary, "that's the end of my medicines."

Sending them away to the baths is still the refuge of the baffled therapeutist. Apropos of the hot baths of France we find a humorous account of their origin in Rabelais, who was a physician, as well as a philosopher and a wit, and whose epitaph as composed by himself was:

*"Cordiger et Medicus, dein pastor et intus obivi;*
*Si nomen quaeris, te mea scripta docent."*

But Rabelais' humor is usually entirely too Rabelaisian for the canons of good taste to permit their intrusion in a modern essay, and the reader is modestly referred to the youthful Garagantua's learned and very numerous experimentations with torcheculs. His father Grangousier was delighted with the results and swore a mighty oath that he should be made a doctor of Belles Lettres. Garagantua's followers are still at it telling of their labors in our Archives and Centralblatts and Proceedings, though they do not all of them bring their labors to such a brilliant and successful conclusion. Apropos of the youthful student in medicine, perhaps one of the best types of Molière's caricatures is to be observed in his description of the pedant. The patient's doctor, a fond father, thus commends his son and pupil:

"Monsieur, it is not because I am his father, but I can assure you that I have reason to be satisfied with him, and everyone who knows him agrees there is no evil in him. He never had a very vivid imagination and nothing of that liveliness of wit which one sometimes sees, but it is exactly on that account I have augured well of his judgment,

a requisite attribute for the practice of our art. When he was little he was never what might be called playful and wideawake, but always calm and peaceful and quiet, never saying anything and never indulging in any childish play. It was with great difficulty he was taught to read, and he was nine years old before he knew his letters. Very good, said I to myself; the late bearing trees are the very ones which have the best fruit. It is very much more difficult to engrave on marble than to scratch on the sand. but things are preserved there longer, and this slowness of comprehension, this lack of imagination is the mark of future good judgment. When he was in college he had some trouble but he struggled against his difficulties, and his teachers were always praising him for his perseverance and his industry. At length, by sticking at it he came out gloriously and got his degree. And now I can say that for the two years he has been in our society there is no member who makes more noise in our discussions. He has made himself feared, and nothing comes up but he is ready to argue to the last breath. He is firm in dispute, and a very Turk in his doctrines. He never gives up his opinions, and carries an argument to the very last resorts of logic, but. and this is especially gratifying to me, and in it he follows my example—he clings blindly to the opinions of the old writers, and he will not understand nor listen to the arguments and pretended discoveries of our age concerning the circulation of the blood and other opinions of that kind."

We all of us know that young man. We have sat at lectures with him. We have heard him describe the anfractuosities of the temporal bone and reel off the classical signs of lobar pneumonia, and we have watched his subsequent successful career in life with mild wonder at the inscrutable decrees of a merciful Providence.

We have seen that Molière's doctor discovered that the malady was not in the patient's blood by bleeding him fifteen times. Dr. Sangrado never arrived at such a hasty conclusion. Dr. Sangrado is perhaps famed above all other doctors of satire. In him Le Sage held up to ridicule the practice of venesection. A few years ago the hot water craze reminded us of him, for his only other prescription than bleeding was advice to drink unlimited amounts of hot water. Says Gil Blas: "He sent me for a surgeon and had drawn from my master six good dishes of blood. Then said he to the surgeon, 'return in three hours and take as much more, and to-morrow we will commence again. You can't bleed a patient too much.' He said we must also give warm water every moment, assuring us that water drunk in large quantity might pass for a true specific against all kinds of diseases." Gil Blas' master soon had occasion under this treatment to send for a notary to make his will. "The notary," says Gil Blas, 'was a gay little old chap who was always joking; he asked me what doctor was attending my master. I told him it was the doctor Sangrado. At this name, suddenly seizing his hat and cloak, he cried; 'Great God! I have no time to lose, for that doctor is so expeditious that he don't give his patients much time to send for a notary. That fellow has cheated me out of a good many wills."

Sangrado's treatment was in vogue for more than a hundred years after Le Sage's great novel was given to the world, but it is probable that the grim jests therein recorded had as much to do in abolishing this horrid abuse of the medical art as any advance in the knowledge of physiological principles and of clinical facts. It is also probable that these grim jests have caused many a pneumonia patient to die of late years for the want of a little judicious bloodletting. These "gay little notaries" are still among us, cracking appendicitis jokes and drawing cartoons which occasionally make us a little tired, as they must have done our forbears at all stages of the world's advance in civilization.

Molière deals with the subject thus in "L'Amour Medecin." The heroine's maid is very much provoked that her master has called in four doctors to treat his daughter who, as the maid very well knows, is only lovesick. "Isn't one enough to kill a body? Can't your daughter die without the help of these gentlemen? Why I used to know a man who could prove, by good reasoning too, that it is not proper to say that a person is dead of a fever or a pneumonia, but that he is dead of four physicians and two apothecaries. My goodness! monsieur, our cat has lately been suffering from a jump she made from the top of the house. For three days she could not eat or lift a leg; but it is very lucky there are no *cat* doctors. They would have fixed her. They would have been bleeding and purging her yet." It seems veterinarians were unknown then, for I think it is Boileau who said: "Among them also, the animals I mean, no physician has ever arisen to poison the woods with his murderous art." The cat would not have gotten off so easily now. Lisette recognizes one of the doctors as having attended one of her fellow servants. The doctor asks: "How's the coachman?" "Quite well, I thank you. He's dead." "Dead?" "Yes." "That can't be." "I tell you he is dead and buried." "That's impossible. Hippocrates says that these kinds of disease only terminate on the fourteenth or the twenty-first day, and it is only the sixth day since he was taken ill." "Hippocrates may say what he pleases, but the coachman is dead."

In one of Molière's doctors consultations how familiar to us is the opening speech of the smooth and sly old consultant: "God forbid, Monsieur," says he to the man who has called him in, "that I should attempt to add anything to what you have just said, since you have so well described the signs, the symptoms, and the causes of the patient's malady. (The patient was supposed to be crazy.) The arguments which you have advanced are so learned and so admirable that it is impossible that he should not be either insane or a hypochondriac; and if it should turn out that he should not be so, it is evident that he must shortly become so—from the clearness of the things you have said and the force of the arguments you have used." The eloquence of the suave and artful consultant and his evident desire to please his medical friend is sometimes observed among the laity even as far back as Cicero, for he says in his letter to Servius, on recommending a physician to him. "Therefore, I especially desire and beg of you that you will take care that he well understands that I have spoken well of him, and that my influence has been of great advantage to him. For this I shall be very much obliged."

The jokes of the laity in regard to the etiquette of doctors' consultations have their archetype in the remark of one of Molière's consultants. "The formalities should always be observed whatever may happen—for a dead man is only a dead man, after all, but a point of etiquette neglected is a great prejudice to the interests of the whole body of the profession."

One of the consultants in "L'Amour Médecin" says to the distressed father of the patient: "After all this is done, however, you should know that your daughter may die, but you will at least have the consolation of knowing that your daughter died

under the proper treatment." It is said that Molière drew the four physicians in this comedy from life, and that when represented on the stage they even wore masks made to resemble their originals. Macroton, he of the doleful prognostics and slow speech, was Guérant, first physician to the Queen.

After the faculty had given their advice ending with the grave prognosis just recorded, how natural it is to find the family calling in a mind curist, who in this instance is the disguised lover and who, after a careful examination, says with admirable sagacity: "I recognize that it is the mind of the patient which is diseased, and that her whole illness comes from a disordered imagination and a depraved desire to be married." Much gynecological learning is here displayed.

It is impossible for us entirely to free ourselves from the prejudices which we insensibly absorb from our environment. In spite of ourselves, in spite of the garnered wisdom of older and higher civilizations, and in spite of the fact that we acknowledge and do homage to that wisdom publicly our ideals are chiefly those of the multitude in which we are submerged. We are still able, thank God, to understand the joy which filled Abou Ben Adam's soul when he found the angel had written his name in that book of gold at the head of those whom the love of God had blessed, because he loved his fellowmen. Nevertheless we must confess to ourselves that we and our fellowmen would have been so interested in the binding of that volume, that we might have missed the names inscribed on its pages. Across the stamp "Success," with which our commonwealth seals the obituary notices of its foremost doctors, we involuntarily look for that serpentine mark which heads the bankers' row of figures. Among Chaucer's pilgrims there was one of our craft, and in the lines describing him, the old rhymster is particularly happy:

"With us there was a doctor of Physik,
In all this world ne was there mon hym lik
To speke of Physik and of Surgerye
For he was grounded in Astronomye.

"He knew the cause of everich maladye
Were it hoot or cold or moist or drye,
And where they engendered and of what humor.
He was a very parfit praktisour."

. . . . . .

"His study was but litel on the Bible.

. . . . . .

"And yet he was but easy of dispence.
He kept that he wan in pestilence.
For gold in Physik is a cordial.
Therefore, he loved gold in special."

Abou Ben Adam's ideal may be the highest, and the idea of Chaucer's doctor may still be the ruling one, but one of Molière's notions of our art should not be entirely ignored.

It may be well before we part with Molière to know what apparently he really thought of our art. It certainly seems to me instructive and suggestive.

The brother of the Malade Imaginaire remonstrates with him against his infatuation for doctoring, and incidentally airs his own and doubtless Molière's opinion of doctors:

"The most of them are accomplished, can talk in fine Latin and give Greek names to all diseases, divide them and define them, but as for curing people—that is something they know nothing of. The whole merit of their art consists of presumptious folly, of a special sort of chatter, which gives you words for explanations and promises for results." Then he goes on to say that "there are some among them who truly believe in the popular estimate of themselves and profit by it, and there are others who profit by it without believing in it at all."

The patient exclaims in wonder, "Well, what should a man do when he is sick?" "Nothing at all, only keep quiet. When a doctor talks to you of aiding, of rescuing, of soothing nature, of taking from her that which is injurious, and of giving her that which she lacks, of re-establishing, of placing her in full possession of her functions; when he talks of purifying the blood, of soothing the intestines, and cooling the brain, of depleting the spleen, of relieving the chest, of rectifying the liver, of strengthening the heart, of preserving the animal heat, of having secrets for prolonging life for many years, he is relating to you the romance of medicine. For when you get down to the truth of it, in practice you don't find anything of the kind. It is like one of those beautiful dreams which only leaves behind it disgust at having believed in it."

Notwithstanding this tirade against the doctors, Molière in this play puts his own defence (and we see he has it again from Petrarch) in the mouth of the candid brother who says in reply to criticisms of Molière's satires:

"It is not the doctors whom he jokes, but the ridiculous side of doctoring." Probably the doctors of that day did not hold that charitable opinion of him.

Molière probably died of a pulmonary hemorrhage. He was seized with the fatal attack as he was playing the part of the Malade Imaginaire. It was the sad irony of fate. Perhaps he was trying to convince himself that his sufferings were only the figments of his imagination when he wrote this, his last great comedy. He there gave a parting blast to us doctors and, like the ghost of Turnus, "went howling to the shades below."

After all, as you see, the criticisms and complaints which arise from struggling humanity to the gods have been very much the same in all ages.

"And see," says Panurge, "how the times are out of joint. We trust our souls to theologians who, for the most part, are heretics; our bodies to the physicians, who all abhor drugs, and our property to the lawyers, who never sue one another."

A singular example of this remark, as it applies to doctors, is noted in the death of Dupuytren, the greatest surgeon of his day. He died of an empyema, refusing operation with the remark that, "he would rather die by God's hand than by that of a surgeon."

But if there is no limit to the glimpses we might take at the jokes made at our expense in literature there *is* a limit to your time and patience. I do not feel that I am permitted to encroach on either any further, but in closing, as an excuse for our existence at all, I may quote the saying of a witty Frenchman:

"As long as men may die, and as long as they love to live, the doctor will be ridiculed—and well paid."

But a nobler retort was that of another witty Frenchman:

"*Railles donc, calomnies à votre aise le médecin, cela ne l'empêchera pas à l'occasion, de remplir avec zèle sa noble mission qui est de guérir quelquefois, de soulager souvent, et de consoler toujours—des ingrats et des indifférents.*"

44 WEST FORTY-NINTH STREET.

**Poisoning among Workmen in Great Britain.**—Nine hundred and thirty-six cases of poisoning were reported among British workmen last year. One hundred and eighty-nine of these were due to white lead, and 106 to pottery.

# SOME EXPERIENCES WITH ICHTHYOL IN PUERPERAL FEVER.

By J. D. MacPHERSON, M.D.,
NEW YORK.
PHYSICIAN TO FLUSHING HOSPITAL; INSTRUCTOR IN THE NEW YORK POST-GRADUATE SCHOOL AND HOSPITAL.

FEW things are more exasperating or cause more anxiety to the busy practitioner than cases of puerperal fever, occurring as they do at times after every precaution has been taken to secure perfect asepsis. We know that theoretically puerperal sepsis should never occur, but practically the careful physician does meet it occasionally.

An eminent Dublin obstetrician, connected with a large maternity hospital there, said a while ago that in the worst cases of sepsis he had ever seen no instruments had been used; there had been no unusual interference, the placenta was perfect, there were no lacerations, and the strictest antisepsis had been maintained.

Such a case occurred in my practice two years ago: I. M., multipara, was confined May 23, 1901. Patient was of rather delicate build, anæmic, but, with the exception of several mild attacks of malaria, was in a fairly healthy condition. Her first confinement, four years previous to this, was normal in every way. With the exception of the case being a face presentation, this labor was also normal. No instruments were used, there were no lacerations, only pitcher douches were given, and the placenta was as perfect as any I have ever seen. Everything was apparently normal until the tenth day, when, without any known cause, the patient's pulse and temperature began to rise, and she complained of feeling ill. There was no suppression or other change in the lochia at this time. As soon as I had satisfied myself that the trouble was not due to malarial poisoning, vigorous measures were employed at once to combat septic infection. The uterus was swabbed out with carbolic acid and iodine; uterine douches were given, the patient was put on a highly nutritious diet, and stimulating and supporting measures were administered. Among other remedies employed Credé's ointment was used in large quantities—in fact, it was rubbed in by the ounce, but, notwithstanding the most active treatment, my patient rapidly developed a very severe form of sepsis and was soon in a desperate condition. She had a chill, followed by a temperature ranging from 104° to 105°, and profuse sweating every twenty-four hours, and, as the case progressed, at shorter intervals. She lost flesh rapidly and became so weak that the slightest exertion completely exhausted her. There was now a profuse purulent discharge from the uterus; certainly the outlook seemed very gloomy, and nothing appeared to have any effect upon the progress of the disease. At this point I concluded to give ichthyol a trial, knowing what wonderful work it did in other forms of sepsis. The uterus was irrigated with a gallon of 1–4000 bichloride solution, and then packed with moist sterile gauze saturated with equal parts of ichthyol and glycerin, which was left there for twenty-four hours. It may be here stated that ichthyol and lanolin had been applied externally to the abdomen before this, but without effect.

The next morning I was delighted to find that my patient had missed her chill; she had slept several hours and was feeling much better. The temperature had dropped two degrees and her pulse was much improved.

The packing was removed, a uterine douche was given, and another packing inserted. The next day the temperature was only 99⅖° and the pulse 90. My patient did not have another chill during her illness, and, although very weak, her impr was steady from this time on. Such ma provement following immediately after th ichthyol in this patient, I concluded to try if another case of the same kind presented i

M. H., confined April 26, 1902, a midwi Sepsis came on in this patient twelve hours apparently normal labor. This was the eleventh confinement, and with the exce one instrumental labor, she had never exp any trouble before. There were no lacera the maternal parts, and the midwife repor the placenta was perfect. I found the depressed with a rapid pulse and a tempe 104°, which rose to 105° in the evening. T no tenderness over the uterus or chang lochia at this time. The uterus was irrig bowels were thoroughly moved, and large quinine were given. On the following m found patient's temperature was nearly her general condition worse. A large uterin was now given, and the uterus was pac ichthyol gauze, as in the previous case, following morning I could hardly believe mometer when I found that it registered and her pulse 90. She felt better and he condition was much improved. The dou repeated, but instead of packing the uterus drachm of ichthyol, diluted with equal sterile water, was injected into the uter next day my patient's temperature was 9 she said she began to feel like herself again this time improvement was rapid, and within her condition was apparently normal.

B. M., primipara, my third case, was serious one, complicated with typhoi Patient was delivered of twins August Forceps case, there were no lacerations, the was normal. The following morning tem was 104°, pulse 110 and feeble. The abdo tympanitic, but not painful. The bow loose, the lochia normal. The evening tem was 105° and patient was delirious and As there were a number of cases of typh in the neighborhood a specimen of her b taken for examination and gave a positi reaction.

Septic symptoms did not develop until day in this case and were ushered in by chill, a higher temperature, followed by and the lochia soon became mucopuru this time her condition was so grave that little hope of her recovery. The uterus gated and packed with ichthyol gauze other cases. The following day the tem was lower, the patient did not have a discharge was somewhat less. The icht repeated and was followed by a decided ment in the uterine tenderness and The ichthyol was repeated a number of this case. This patient had a very storm it for five weeks, but finally made a good notwithstanding a sharp intestinal hemor believe ichthyol had more to do with s life than anything else; for when the sep toms appeared she seemed completely ove by the poison, but when they were und she rallied and had vitality enough to typhoid poison. Incidentally it may be that the twins are fine babies. My p pregnant again and expects to be confin a few months.

N. L., primipara, confined December This patient infected herself from a pus tu was so large that it complicated labor a

delivery very difficult. Septic symptoms came on almost immediately and were severe. The temperature ran between 104° and 105° and for several days her pulse was 120. The lochial discharge became purulent at once, and a tumor which was almost as large as an orange could be felt in the left iliac fossa. Patient had rigors and severe sweating and became very feeble. No packing was used in this case. The uterus was irrigated and a drachm of diluted ichthyol injected. Little or no change was noticed in the uterine discharge, but the temperature dropped two degrees and never rose above 102 after the first application. The pulse improved in quality, and patient expressed herself as feeling much stronger. This patient was quite ill for two weeks, but gave no particular anxiety after the first week. The tumor in the iliac fossa gradually grew smaller, and in ten days could be felt with difficulty. The purulent discharge continued for several weeks. The patient had rather a tedious time of it, but finally made a good recovery.

M. M., multipara, confined March 30, 1903. Labor was normal with the exception of an adherent placenta, which was delivered with difficulty. On account of this, unusual care was taken to keep the parts aseptic, nevertheless on the third day the pulse rose to 100 and temperature to 103°. The lochia was suppressed and patient gave all the symptoms of septic intoxication. The uterus was irrigated and diluted ichthyol injected. The following morning her temperature was 100° and her pulse 84. Patient felt much better. Improvement was so rapid that on the tenth day she felt perfectly well and asked to be allowed to sit up. She had plenty of milk for her child. Pulse and temperature were normal, and there was nothing about her appearance to lead one to think there had been anything abnormal about the puerperal period.

The remarkable results which have followed the use of ichthyol in these five cases, three of which were desperate ones, has led me to believe that it is a valuable remedy in this dangerous disease. The objection may be made that the packing had as much to do with patient's improved condition as the ichthyol, but in two of the cases reported no packing was used, and the drug was simply injected into the uterine cavity after free irrigation. I am aware that at least one case of severe depression following the application of ichthyol to the cavity of the uterus has been reported. But no such untoward symptoms appeared in any of the cases here mentioned. However all these patients were being well stimulated with strychnine ammonium carbonate at the time. Instead of any unpleasant symptoms arising, exactly the opposite were observed; in fact, the drug acted like a specific. Not only were the pulse and temperature reduced, rigors ceased and discharge lessened, but patients had a feeling of well-being following the use of ichthyol, which was a pleasant contrast to the appearance of mental and physical suffering which one often witnesses in these cases.

College Point, Borough of Queens.

**Prevalence of Tuberculosis among the Mentally Affected.**—Dr. H. Timbrell Bulstrode says that among 70,958 lunatics treated in Prussian asylums during 1901 there were 5,128 deaths, or a fatality rate of 7 per cent. The incidence of tuberculosis was heaviest upon the idiots, as out of 12,212 idiots treated during 1900, 462, or 4 per cent., died, and of these, 259, or over half, died from lung diseases.

## THE SURGICAL TREATMENT OF COLITIS.*

By C. L. GIBSON, M.D.,
NEW YORK.
ATTENDING SURGEON ST. LUKE'S AND THE GENERAL MEMORIAL HOSPITALS.

At the present time the application of surgical measures to the relief of colitis usually begins where medical measures leave off and so it fails, the surgeon having an opportunity to treat only the severer and more hopelessly chronic cases. I trust that in the future surgical measures may find a place as a prophylaxis against acute conditions assuming such permanently unfavorable phases. I realize, however, that this end can be attained only if surgical art can offer methods giving a reasonable certainty of improvement, yet devoid of the risks and possible bad after-results inherent to a serious surgical operation.

In my experience the severer cases of colitis, whatever the etiology, involve the greater part, usually the whole, of the large intestine. Topical treatment from below under these conditions is necessarily inefficient, so to treat the whole, and not the part alone, surgical aid may wisely be sought for the cases not yielding to the curative effects of time, physiological feeding, and the administration of medication of unproven efficacy.

Prior to the introduction of a method which will be the chief subject of this paper, the surgical relief of colitis, consisted of a single measure, the establishment of an artificial anus to give physiological rest to the bowel and for the treatment of the ulcerated areas by appropriate flushing with cleansing, or antiseptic or supposedly specific solutions. A partial artificial anus, that is a simple lateral opening in the gut gives a maximum amount of discomfort, while perfect physiological rest can be obtained only by a complete artificial anus—namely, severing the gut and fastening its upper end permanently to the surface of the body, necessitating for its future repair one of the severest operations practised in abdominal surgery. It is no wonder then that surgical measures of this kind fail to appeal, either to the patient or to the conscientious practitioner whose responsibility it is to conduct such a case. It is my belief that there must be a middle ground between these two extremes—medical treatment incapable of meeting certain given conditions, and the repulsive and hazardous features incident to an artificial anus. On this basis, in 1900, I devised an operation which made direct treatment of the entire colon possible—simple in its performance, and devoid of any discomforts to the patient; and is performed carefully, attended with a minimum of danger. Its application was first demonstrated by the kind courtesy of Drs. P. R. Bolton and F. H. Marloe in accepting my suggestions, as it was not till considerably later that I had an opportunity to perform it on a patient of my own.

The cases and technique have already been described by me in a paper entitled "The Creation of an Artificial Valvular Fistula for the Treatment of Chronic Colitis," read in Boston, March 5, 1902, and published in the *Boston Medical and Surgical Journal*, September 25, 1902.

Described briefly, my plan is as follows: a small intermuscular incision is made over the caput coli. Then, reproducing the technique of the Kader gastrostomy, a catheter is introduced into the bowel through an opening just large enough to admit it. By using two tiers of sutures, the tube is infolded into the cæcal wall, absolutely guaranteeing against any leakage, and the bowel is finally secured to the

*Read before the New York County Medical Association, May 18, 1903.

abdominal wall. So perfect is the technique that the irrigations of the colon might be begun at once, but it will be wisest to wait forty-eight hours. After the tube has been in place a week, it is removed, when the essential feature, the artificial valve, becomes operative. For so soon as the tube is removed, the infolded cone of intestinal wall prevents absolutely the exit of intestinal contents. From now on so soon as the patients strength responds to the beneficial effects of the operation, he can continue the treatment while gradually resuming his ordinary mode of life; for after ten days he can leave his bed, all dressings are discarded, as there is no leakage, and the tube is only required as described.

The further treatment consists of the reintroduction of the tube two to four times a day and flushing of the gut by appropriate solutions, chief reliance being placed on saline solution for cleansing; and of gradually increasing strengths of nitrate of silver. To obtain permanent closure of the fistula, it is only necessary to discontinue the treatment: for by omitting to pass the catheter, after a few days, the valvular infolding of the walls becomes permanent and the patient's surgical condition is at an end.

The cases so far treated, although few in number, have shown a striking response to the treatment, with rapid amelioration of the character of the stools, decrease in their frequency and prompt constitutional improvement and gain in strength and weight.

A modification in the technique of my operation has lately been practised by Dr. Weir by using the appendical stump instead of making a valvular opening. Its seeming advantage is that it makes a very simple operation still simpler. The necessary and essential feature of my operation, the valve formation, being wanting, the after-treatment is far less agreeable to the patient, as he is subjected to the inconvenience of leakage, and the necessity of a prolonged wearing of a tube and dressing. The very small hole also allows of less freer flushing. Moreover the patient has to undergo further treatment in order to close the fistula.

Contrast this picture of a simple, cleanly, and yet efficacious course of treatment, involving only ten days' stay in bed, with the misery of the unfortunate victim of an artificial anus wallowing in fæces for months with the prospect of a more or less severe operation to be undergone before he can be restored to health, and I think you will justify me in my attempts to put the surgical treatment of colitis on a new basis.

Summing up, I would say that in this operation just described the results have been such as to justify the hope of marked amelioration or cure of the symptoms.

It is devoid of every disagreeable feature of an artificial anus.

It calls for only a short confinement to bed.

If a prolonged course of treatment is required, it may be carried out if necessary by the patient himself.

A change of climate, so often beneficial, is made possible.

Its performance is perfectly simple and safe.

The intermuscular incision greatly reduces the risk of a subsequent hernia.

The prompt closure of the fistula is certain and spontaneous.

---

**Aphasia as a Result of Heat Exhaustion.**—R. E. Weigall reports the case of a patient who was prostrated, almost pulseless, with a cold surface of the body and a temperature of 95°, as a result of walking half a mile in the hot sun, carrying a bag. Her condition became much worse—there was absolute aphasia, agraphia, alexia, partial arm and face paralysis, and indications of a progressive meningitis and approaching death. Trephining was performed over the speech center, the dura mater was incised, and an extensive intrameningeal hemorrhage made its way out. Free irrigation with hot saline solution was made, and a small tube was inserted, and removed on the third day. Improvement began at once after the operation, and in a week the patient had fully recovered.—*The Australasian Medical Gazette.*

**Autointoxication and Its Relation to Disorders of the Nervous System.**—Benjamin Leon Wyman says that the modern idea of the nervous system appears to be that there is a constant streaming of nervous energy along neuron after neuron as along link after link of the sensory motor chain. If this theory be correct, it is absolutely essential, in order that the neuronic mass shall function properly, that there be physiological contiguity between the various nerve units, and any condition which hinders their proper connections interferes with the transmission of nerve impulses. Man contains within himself a "laboratory of poisons," and whatever the name given them, ptomains, leucomains, alloxuric bodies, xanthin, etc., they are all more or less toxic in their effects. Autointoxication is dependent largely upon the ingestion of more of the proteids than the digestive organs can appropriate, and as a result effete products accumulate. Neurasthenia, migraine, puerperal eclampsia, epilepsy, neuroses following operations, and many other diseases of the nerve centers are due to this autointoxication, in some cases acting on a hereditary instability of the neurons. The author concludes: (1) That autotoxæmia is an etiological factor of great importance in many functional disorders of the nervous system. (2) That these poisons produce symptoms by either lessening, retarding, preventing, or arresting the functional capacity of the nerve center by interference with the transmission of nerve impulses. (3) That the disturbances involve both the central and peripheral neurons. (4) That repeated and chronic autointoxication may lead to structural alterations in the nerve cells and fibers.—*Alabama Medical Journal.*

**The Results of the Treatment of Four Hundred and Eight Cases of Typhoid Fever, with a Report of Experiments with a New Method.**—H. C. McCormick states that the local application of guaiacol for the reduction of temperature has proved so effective and safe a remedy, that after having applied it 3,150 times, he heartily recommends it. The right iliac region is cleansed and dried, and alcohol applied. From five to ten drops of guaiacol are slowly dropped on the surface and rubbed in with the hand from ten to fifteen minutes. The part is then covered with oiled paper. The antipyretic effect lasts from two to four hours. The author treated four patients with acid sulphate of sodium. They were admitted on or before the seventh day. The temperature charts showed, from the time they came under the influence of the sodium salt, a fall of about one degree, and the morning remission was almost entirely abolished. The author finds that in a solution of 1 to 300 the acid sulphate of sodium is germicidal to typhoid bacilli, increases leucocytosis, and thus helps nature to combat the disease, neutralizes typhotoxin, and in a measure lessens delirium and other symptoms attributed to this poison, prevents, to a great degree, the congestion of Peyer's patches, and by this means prevents to some extent hemorrhage and perforation. It will resist bacilli or toxin in any part of the body, and greatly lessens the complications of the disease. It is a prophylactic, and is not neutralized in the stomach. It replaces physiologically the deficient hydrochloric acid. It furnishes an abortive treatment. It may be used to purify contaminated drinking water by allowing the solution to stand from twelve to fifteen minutes before being taken.—*The Therapeutic Gazette.*

## DIAGNOSIS OF EARLY TUBERCULOSIS.

IN the *Wiener medicinische Wochenschrift*, Nos. 7-10, 1903, Dr. Martell points out the necessity of early diagnosis, as only in the beginning can the extension of the infection from the original foci be prevented, and the severe damaging of the whole organism by toxins be hindered. Reviewing the criteria available for early diagnosis, the author finds conflict of experience as to the value of the orrhodiagnosis of Arloing and Courmont, Koch's tuberculin, and the eosinophilia of the sputum observed by Teichmüller. The last is, however, an aid; and of great significance in a suspected fluid is the presence of many small lymphocytes, since staphylococcus, streptococcus, and pneumococcus infections involve the presence of many polynuclears. Thrown back then chiefly upon clinical signs, the author lays special stress upon the nervous symptoms which have hitherto received too little consideration. Hammer has shown experimentally that inoculation with tuberculosis produces, both in the peripheral nerves and in the central nervous system (in the latter with great regularity) alterations which appear very early, ten to nineteen days, and involve the cells of the anterior horns, thus producing muscular weaknesses which may, though rarely, proceed to complete paralysis. These tuberculous myasthenias and neurasthenias have the characteristic that they make their appearance principally at the outset, and after some time vanish, to reappear upon the slightest over-exertion. Moreover, we find in the peripheral nerves, palpable, objective evidence in the way of painful pressure points, that the tuberculous toxin has attacked the posterior roots and columns. These phenomena are demonstrable in every case of early tuberculosis (and can, therefore, be regarded as indubitable, pathognomonic signs), while they are absent in chronic and advanced cases. Sometimes unilateral, sometimes bilateral, now in the upper, now in the lower, extremity, these pressure pains give evidence as to the locality of the focus, while the degree of the hyperæsthesia serves as a measure of the amount of toxin generated. Of special importance is the unilateral plexus pressure pain which, according to Schmidt, is a certain early symptom of pulmonary tuberculosis and of the initial hæmoptysis; and if it become extraordinarily violent, we have to think of an impending hemorrhage. On the other hand, the complete vanishing of this pain implies an unfavorable prognosis. These facts find their explanation in an early sensitiveness of the nerves (the correlate of neuritis), while their integrity is preserved, and a later obtuseness of sensibility when degenerative changes have taken place. If, then, rather heavy pressure over the intercostal spaces brings out flinching and complaint of pain, this is so characteristic that we may regard it as an extremely certain sign of gland disease, all the more if the phenomena cannot be elicited on the opposite side. Similarly, investigation of the abdomen will reveal disease of the mesenteric glands. The existence of an abdominal focus leads to a series of well characterized painful pressure points. According to Faber, two such points exist; one between the xiphoid and the navel, and one between the navel and the pubis. According to Kelling, a second epigastric point exists, corresponding in position to the pylorus. Inconstant, and often only demonstrable with difficulty, are four points situated around and about 25 mm. from the navel; one on either side, one above, and one below. Constant, like the epigastric, is one point over the ischiatic nerve. Its existence is diagnostically of such importance that we are justified, when it is unilateral, in assuming a definite diseased focus on the corresponding side. This pain is demonstrable lower down, over the tibial nerve, and over the plantar at the end phalanx of the great toe. On the side of the patient it gives rise to the most various complaints, such as of too tight shoes, and of a feeling of cold or numbness. Not infrequently crossed pressure points are observed. Thus right ischiatic pain, left plexus pain, and pain in the left bronchial gland region warrant the diagnosis of tuberculosis of the right mesenteric and left bronchial glands.

Turning now to the avenue of contagion, the author argues with considerable plausibility in favor of the primary rôle of the lymph glands as against the secondary place usually assigned to them. Thus, in his opinion, pulmonary tuberculosis does not, in general, result in infection of the bronchial glands, but is the outcome of the initial infection of the latter. He supports this view chiefly from three sides, citing observed cases of transmission from mother to fœtus, via the (tuberculous) placenta; and bringing forward statistics showing the great frequency on the one hand, of heredity in the histories, and on the other, of glandular involvement in the autopsies. Infection spreads by (*a*) the lodgement of bacilli in a gland, leading to local tubercle development which (*b*) gradually obstructs the lymph flow, and finally results in (*c*) the establishment of a collateral or retrograde lymph circulation from the infected territory which (*d*) infects the next adjacent gland territory, and (*e*) ultimately more remote regions. Infection of organs is thus regarded as secondary to that of their glands. Indeed, Aufrecht has recently shown that in pulmonary tuberculosis the initial lesion begins as an involvement of the walls of blood vessels which have a cheesy gland at their hylus, and has found tubercle bacilli in the thickened walls.

**A Woman Ship Doctor.**—According to a British weekly journal, a Mlle. Sarah Broido, a young woman physician, has obtained an engagement as ship's doctor on board a steamer plying between Marseilles and Algiers. Mlle. Broido is the first French medical woman who has been employed in such a capacity.

## INSPECTION OF THE TEETH AND GUMS AS AN AID TO DIAGNOSIS.

*The Medical Times and Hospital Gazette* of August 15 refers to a paper published on this subject by Campbell in the *British Dental Journal* of June 15. The state of the mouth is to a considerable extent an index to the condition of a person's health. If an individual is free from bodily ailments, then, as a rule, the teeth and gums are sound and healthy. Campbell says that "the state of the teeth must exert a constant influence upon the condition of the body; and as truly the general condition of the body exerts an important influence upon the state of the teeth, and it is this close relationship of the state of the mouth to the state of the general health that makes the work of the dental surgeon of such paramount importance and interest to the physician." By some it is asserted that morbid states of teeth, gums, alveoli, etc., are the causes of certain deadly diseases. Hunter has endeavored to show that oral sepsis, having its origin in long continued and neglected carionecrotic conditions of the teeth is the cause of pernicious anæmia. He argues that this fatal malady is due to a special infection of the digestive tract, caused by oral sepsis. Campbell does not deny to oral sepsis some contributory power, or even that in some cases that power may be considerable, but is nevertheless convinced that it is not only not responsible for the causation of the disease but plays a quite unimportant part in this connection. Since the publication of Hunter's book upon pernicious anæmia, the author has carefully investigated the condition of the mouth in every case that has come under his notice, and has found that although in the majority the gums were spongy, the teeth loose, with pus welling up by their sides and the gums receding, yet in others the teeth and gums have shown no sign of disease. He, therefore, concludes, as the result of his own observations, that such oral conditions are rather the outcome of than the cause of the disease.

Reference is made to the sweet apple-like odor with which the breath of patients suffering from diabetes mellitus is impregnated. The dental condition most frequently met with in cases of this disease is a loosening and painless shedding of sound teeth. Dental caries, gingivitis, and spongy or bleeding gums also occur at times, but these conditions are, of course, not such distinctive features as is the former.

It is noted that the changes in the teeth due to the imperfect calcification of the enamel dentine, often supply a valuable record of the life-history of the patient.

Other conditions of the mouth which will serve as a useful guide to the physician in making a diagnosis are, says the author, the ground-down teeth of the gouty, the occasionally met with dental periostitis of the rheumatic, and caries or impaction as a cause of various ailments of children. Again, a suspicion as to the presence of tuberculous disease may be aroused from the pallor of the mucous membrane, or of Addison's disease from the presence of pigmentation. The effect of certain poisons, in producing marked changes in the jaws and gums, is pointed out by Campbell.

The condition of the teeth and gums affords satisfactory testimony as to the general state of health of an individual, and is an invaluable aid to the physician in making a diagnosis. However, most medical men would probably agree rather with Campbell than Hunter in thinking that oral sepsis is not the cause of but the effect of disease. At the same time the great importance of keeping the teeth and gums in as good a condition as possible must not be minimized.

---

### Sporozoan Origin of Dengue.

In the *Journal of Tropical Medicine* for July 1 Dr. H. Graham of Beyrouth, in an article supplementary to that published previously in the Medical Record, describes his successful experiments in transmitting dengue by mosquitos which had fed upon patients suffering from this disease, and his discovery in the red blood cells of a protozoan parasite. Beyrouth and the villages on Lebanon contain the mosquitos *Culex fatigans* and *Stegomyia fasciata;* the latter being less frequent in the villages. By killing all the mosquitos in a room daily by chlorine gas, and moving the patient into the room thus cleared, it was possible to preserve a child from infection by its mother though nursing continually through the attack. The same precautions sufficed to prevent infection of three children who played in the room of, and slept in the same bed with a fourth ill with the disease. Again, the same precautions operated to prevent the infection of any others of the family by the father ill with dengue. Three out of four men who slept under a netting with mosquitos infected by feeding on a dengue case contracted dengue, the fourth and immune man having had the disease before. To settle the question beyond doubt, infected mosquitos were taken to a locality at an altitude of 3,000 feet where the disease was unknown, and two non-immunes were infected by sleeping under a netting with the mosquitos; and these latter being killed no other cases of the disease occurred in the locality. In 1889 the author slept one night in mosquito plagued Beyrouth and then went 4,600 feet up the Taurus range to a mosquito free locality. Sleeping in a cabin with eleven others he alone developed dengue. In handling the infected mosquito his wife was accidentally bitten, and developed dengue after the usual incubation period. Finally, injection of infusion of an infected mosquito's salivary gland transmitted the disease. In all the cases of the disease examined the blood was found to contain an unpigmented protozoan situated within the red cells. A much smaller number of the last were affected than occurs with the tertian malarial parasite. The parasite found resembled *Pirosoma bigeminum* but had not the divided form to which the latter owes its specific name. The most satisfactory results were obtained by examining the blood fresh.

The changes from day to day in the parasite taken from the mosquito's stomach differed in no essential way from those occurring in the patient's blood. A day to day search for zygotes such as are found in malaria resulted negatively, and nothing resembling the fusion of microgamete and macrogamete could be observed either in the blood or in the mosquito's stomach. The evolution of the parasite resembled that of *Pirosoma bigeminum*. Within forty-eight hours after infection by feeding upon a patient on the fourth day of the disease, spores make their appearance among the cells of the mosquito's salivary gland, and spores were found in mosquitos kept alive up to a month after infection. Referring to the reported finding of malarial parasites in the blood of dengue patients

by Stedman of Hongkong, the author thinks that they were the dengue parasites that he found, and not malarial parasites. His pirosoma-like parasite is found in much larger numbers during relapses, but careful examination will reveal it in the first attack. The great mass of patients with relapse have never had malaria, and in Syria at least the mass of them live where no anopheles is present to infect them with malaria. While resembling, under the microscope, the estivoautumnal parasite, the development in the mosquito is too different to allow of its being confounded with the unpigmented quotidian parasite of Marchiafava and Celli. The author concludes that *Culex fatigans* is the transmitting agent, and that the prophylactic measures now in vogue against malaria will suffice to prevent the spread of dengue.

It was reported some time ago that the health authorities of Honolulu were acting upon the mosquito theory of transmission in instituting measures for the suppression of the epidemic of dengue there prevailing.

---

### The Medical Attendance of Londoners.

In a speech at the annual meeting of the Portland Town Free Dispensary, Sir Henry Burdett considers the question of the uses and abuses of medical charity is always with us. In 1895 the various medical institutions in London treated 1,753,611 persons, while in 1902 2,098,905 were treated, an increase of 345,294, though the annual increase in the population was only 60,000. That is, "we find in a single period of twelve months the total number obtaining free medical treatment makes up a grand total representing nearly one out of every two of the population of London. . . . There are not so many as over 2,000,000 really poor people in London. The thirst for hospital relief now pervades all classes. Many well-to-do people argue that after all the hospitals are great public institutions, and as such it is their duty to provide free medical relief for everybody who chooses to take the trouble and expend the time and energy in going to them for it. This continual increase in free medical out relief is wrong." The excuse of the hospitals is that they must not keep anybody away or they may lose an interesting case from a clinical point of view." This is owing to the association of medical education with the hospitals. "In London there is no great medical school as a center. Our system of medical education is in a state of chaos. . . . We have twelve medical schools attached to twelve hospitals. . . . Now if we had one big medical school for all the students of the various hospitals, we should then get our system of medical education into order, and we should hear no more of these attacks of the anti-vivisectionists on the hospitals. . . . I do most heartily hope that the public will combine as one man and set their face absolutely against the perversion of the funds of the hospital to the struggling medical school attached to it." As a remedy the speaker advocates the out-patient department of a hospital's treating only urgent cases; indeed, as it now exists, the out-patient department should be abolished, but the hospitals should arrange to see all cases sent to them by a physician. Thus a system of coöperation between the hospitals and the profession would grow up. After examination the patient would be handed over to the reformed out-patient department—that is, to the provident dispensary.

"At Battersea (it is a little remarkable that the poorest district in London should have shown the way) the working classes and the doctors have united with the Bolingbroke Hospital authorities to carry out a scheme of out-patient relief on the lines I have just explained. Mr. John Burns is said to be proud of it, and well he may be. . . . The Battersea out-patient Provident Dispensary attended 36,564 patients last year. The Battersea out-patient department is a provident dispensary, and the majority of those seen there went first as patients to the hospital, where they were examined and then handed on to the dispensary. The Camberwell Provident Dispensary saw only 7,000, and the Clapham Provident Dispensary 1,435 patients last year, showing that, from the patient's point of view, this system, as carried on at Battersea, is much more widely popular than the present system of medical relief, and it ought to have the candid and immediate attention of all those in charge of our hospitals."

The reason why the hospitals should turn over outdoor work to the dispensaries is that the latter can do it much more economically, the figures showing a cost of two shillings per head for the hospital, as against nine pence for the dispensary. Regarding the reformation of indoor relief, the speaker says that with the assistance of an eminent actuary a scheme is in active preparation whereby for a small annual payment the insured will be guaranteed so many weeks' treatment and care in hospital. This will enable the middle classes to secure treatment as private patients without paying, as many are unable to do, the amounts now charged for private rooms in many hospitals.

---

### Traffic in Cities.

In almost every large city of the world the traffic question is an important one, while in the very large manufacturing cities it is the most difficult problem that confronts the authorities. Various methods are now being adopted to relieve the congested state of the streets of the crowded centers of population, the most popular of which is the construction of subways. London was probably the first large city to introduce this means of facilitating locomotion, and the improvement effected in electrical appliances with the advance made in harnessing electricity to the use of man has immensely widened the field. Subways in which electricity is used as the motive power and for lighting purposes have been made in many places, and the construction of such underground tunnels is proceeding apace. The fact is obvious that measures to draw from the streets a considerable amount of the traffic is an absolute necessity in many towns and it is therefore well that subways should be built. At the same time, however, every precaution should be taken to render these passages healthy and free from danger. Grave complaints have been leveled against the longest London subway, known as the "tuppenny tube," on the grounds of defective ventilation. The most conspicuous example of the menace to life and health afforded by this mode of locomotion was given recently in Paris, when in the subway of that city upward of one hundred human beings perished miserably like rats in a trap. The unhappy occurrence may be looked upon as a warning to those responsible for the building and equipment of subways now under construction. In the first instance the cars used should be fireproof, and in the second place the ventilation of these underground railroads should be as perfect as possible.

In some of the suburban districts of London—according to the *Hospital* of August 1—electric cars have been introduced driven by "the conduit system." The noise made by the approach of a car furnished with its motive power in this manner is compared, by our contemporary, at a distance to the sound of muffled drums, rising gradually to a roar

like that of Niagara. Furthermore, it is pointed out that the gong attached to each car, manipulated by the foot of the driver, emits a most discordant note. The gist of the remarks in the *Hospital* is that these horrible and unaccustomed noises render sleep impossible to the inhabitants of the localities through which the car lines run, and it is feared that the tormented suburbanites will abandon their homes *en masse* and betake themselves to regions where electric cars are unknown. It cannot be denied that the noise made by electric cars is unpleasant, but after a time one becomes accustomed to it. New York has borne with both the elevated railway and the surface electric cars for a considerable period, and its citizens have not been crazed by the noise, nor, indeed, do they appear to have suffered in health. In the same way the people living in the outskirts of London will soon learn to endure with philosophic equanimity the affront offered to their organs of hearing by the electric railroad, and will be able to sleep whilst the cars rush and roar to and fro and the gongs clang throughout the night.

## News of the Week.

**The University of Berne.**—The new buildings of the University of Berne were recently opened. An address was delivered by Professor Kocher. For nearly seventy years the university was housed in an old Dominican friary. In recent years its popularity has increased and the names of 1,200 students are now on its books. The new buildings are charmingly situated on an eminence commanding a view of the whole city and of the Bernese Oberland. The total cost has been £48,000.—*British Medical Journal.*

**The American Association of Obstetricians and Gynecologists** will hold its sixteenth annual meeting in the Northwestern University Medical School Building, Chicago, Ill., Tuesday, Wednesday, and Thursday, September 22, 23, and 24, 1903, under the presidency of Dr. Lehman H. Dunning of Indianapolis. The Auditorium Hotel, Annex, has been selected for the headquarters of the association. Dr. J. B. Murphy, Reliance Building, 100 State street, is the chairman of the committee of arrangements and will gladly furnish any information to members and guests upon application. Dr. Murphy also can be addressed, relating to accommodations, at the hotels. The scientific program contains the titles of thirty-eight papers. During the meeting Dr. J. B. Murphy, by request, will hold a clinic, at which some demonstrations of special interest will be made. Dr. Macdonald will give a demonstration of Emergency Surgery at the Patient's Home, showing operator, assistants, nurses, and equipment in full detail, immediately preceding Dr. Murphy's clinic. All members of the medical profession are cordially invited to attend the scientific sessions. The secretary of the association is Dr. William Warren Potter of Buffalo, N. Y.

**Richfield Springs.**—The bathing establishment at Richfield Springs, N. Y., has recently been sold to a syndicate composed of residents of the Springs and of a number of New York and Philadelphia physicians. Dr. William Baker Crain has become medical director vice Dr. C. C. Ransom resigned.

**American Electrotherapeutic Association.**—The thirteenth annual meeting of this association will be held at the Hotel Windsor, Atlantic City, N. J., on September 22, 23, and 24, 1903. The subject of radiotherapy will occupy a prominent place in the deliberations, the majority of papers to be read during the second day's session being on the Röntgen rays. Members of the medical profession generally are invited to be present. The secretary is Dr. C. E. Skinner of New Haven, Conn.. of whom a program of the meeting and other information may be obtained.

**Anthrax** is reported to have broken out in a herd of cattle on a stock farm in Illinois not far from Chicago. Some apprehension is felt, as much of the milk reaching that city is brought from the region about Palatine, where the disease is reported to prevail.

**A Tuberculosis Aid and Education Association.**—A new association for the alleviation of tuberculosis and the education of the community hopes soon to commence active work in Cambridge, Mass. The constitution says: "This association shall be called the Tuberculosis Aid and Education Association," the object being "to cure at home, if possible, persons suffering with tuberculosis; to relieve with food, as far as possible, all needy tuberculous persons; to educate the entire community in the care and prevention of this disease; to promote the establishment of hospitals for hopeless cases." A deep interest is being awakened in the community, and representative men and women are to be found on the Board of Managers. The Advisory Expert is Dr. Edward O. Otis of Boston. Dr. J. L. Hildreth is chairman of the Advisory Board, consisting of twelve physicians, who will advise the Board of Managers on medical matters. A trained nurse will care for such cases of the poor as need her attention, free of expense, giving instructions as to the disposition of sputum and the formation of healthful habits. Various committees will have charge of the distribution of food, of lectures, of sanitation, etc. The movement is intended to be largely educational, and for this reason there will be on file, open to the public, reports from other organizations working along similar lines, reprints from papers read by physicians before medical and other societies, and pamphlets descriptive of public and private sanatoria. The committee will be grateful to physicians, and others, who will donate any of the above. If possible, they would like three copies, one for the library, one for a special room devoted to advisory conferences, and one for private consultation by the Board of Managers. Communications and donations of literature on tuberculosis may be sent to Mrs. Rufus P. Williams, 86 Washington avenue, North Cambridge, Mass.

**Gift to the Cancer Research Fund.**—Mr. William Waldorf Astor has contributed £20,000 to the British cancer research fund, in response to an appeal made by Mr. Balfour at a public meeting held a few weeks ago.

**Smoking Allowed at West Point.**—Colonel Mills, the commandant of the West Point Military Academy has, with the approval of the Secretary of War, issued an order permitting cadets to smoke during relief from quarters within the barracks limits. The order includes permission to the cadets to purchase pipes and tobacco at the post store. The object of this order permitting pipe-smoking at certain times and places is, it is said, to discourage the clandestine use of cigarettes which is now almost universal. When this order becomes generally known there will probably be a good deal of noise heard from the old ladies of both sexes who have no small vices and few great virtues.

**A Man of Great Size.**—Joseph Grimes, known as "Big Joe" Grimes, believed to have been the largest man in the world, died recently in Cincinnati as the result of a peculiar accident. While riding

in a cab his great weight broke through the bottom, and one of his legs was gashed, the wound refusing to heal. Grimes weighed 754 pounds, and was thirty-four years of age. He was six feet four inches in height, and his body and limbs were of ponderous dimensions.

**Salicylated Wine from Bordeaux.**—The first instance of the Government's refusal to admit to this country adulterated wines, under the Pure Food act, took place a few days ago when entry was refused of a shipment of white wine from Bordeaux, France. Upon analysis this wine was found to contain salicylic acid. Under the Pure Food act entry may be refused to any article of food or drink, the sale and consumption of which are prohibited in the country whence imported. The French Government expressly prohibits the sale of any food substance, solid or liquid, in the composition of which there enters any quantity whatsoever of salicylic acid or its derivatives.

**Abuse of a Lunatic by an Attendant.**—On complaint of Superintendent Pilgrim of the Hudson River State Hospital, one of the attendants has been held for the Grand Jury on the charge of misusing a patient, while the latter lay helpless on a bed under what is called a protection sheet, which is used in cases of suicidal mania. The attendant is said to have confessed that while intoxicated he amused himself by tickling the feet and ribs of the patient and pulling his nose. He is also charged with striking him and blackening his eye.

**Undersized British.**—The Director-General of the British Army Medical Service has issued a report showing that the physique of recruits for the army has declined within the past ten years. He gives the proportion of men in the army under five feet five inches as 106 per thousand in the year 1889 and 132 per thousand in the year 1898. The proportion of men under 33 inches around the chest was 17 per thousand in 1889 and 23 per thousand in 1898. The recruits passed for the service under 120 pounds were 159 per thousand in 1871, 269 per thousand in 1898, and 301 per thousand in 1900.

**Formaldehyde in Milk.**—The arrest and conviction of a milk dealer in Buffalo has brought to the notice of the authorities the practice, said to be common in most of the cities of the State, of adding formaldehyde as a preservative to milk and cream. The milk dealer, when arrested, pleaded guilty. Then he informed the District Attorney where he bought his stuff and gave information to the effect that a New York manufacturer and two Buffalo manufacturers were selling the "preservative" in all the large cities of the State. The District Attorney has instituted proceedings for the arrest and conviction of these men on the charge of selling poison without labelling it as such, which is a violation of the penal code.

**A Sanatorium for Actors.**—Incorporation papers have been filed in Denver for a tuberculosis sanatorium to be reserved for the use of actors who are suffering from consumption.

**Dr. Lapponi Honored.**—Piux X, in order to show his appreciation of the services rendered by Dr. Lapponi to the late Pontiff during his last illness has conferred on him the title of Commendatore. His holiness accompanied the announcement of the honor with a very flattering letter to the doctor, and insisted on personally bestowing the title.

**Sanitary Conditions in Cuba.**—In a recent interview on Cuban matters, which the Washington correspondent of the *New York Times* had with Mr. Louis Garthe, the latter said, anent the sanitary condition of the Island: "By the way, I greatly fear that before long Secretary Hay will be compelled to invite the attention of the Cuban Government to that article of the Platt amendment which relates to sensation. Havana, Matanzas, and some other cities in the west and on the north coast are scrupulously clean; cleaner, indeed, than Washington and some other American cities, but down in the east municipal sanitation is little better than a farce, and sooner or later our Government will be compelled to take official cognizance of their failure to carry out their obligations in this regard." Dr. John Guitéras, we understand, has gone to Santiago to study the blackwater fever prevailing near that city, and if the conditions there are such as stated they will doubtless be reported to Dr. Finlay and rectified by him.

**The Internes at Bellevue Hospital** were in revolt last week against the superintendent of the hospital and the superintendent of the training school, the trouble being caused by the suspension of one of the members of the house staff. They drew up a complaint against Dr. Mabon, the superindent of the hospital, and Miss Delano, the superintendent of nurses, but withdrew the protest on the announcement that the physician would be reinstated. The interne was suspended for having placed another member of the staff, suffering from typhoid fever, in the Townsend cottage instead of in the general ward, without notifying the superintendent of his action. The protest was signed by all the internes of the hospital.

**The Mosquito Plant.**—Some time ago Captain Larymore of the British army reported the discovery of a plant, *Ocimum viride*, the odor of which was said to keep away mosquitos. This was confirmed by Sir George Birdwood in Bombay and then denied by Dr. Prout of Sierra Leone and Sir William Thiselton-Dyer, director of Kew Gardens. But now the *Deutsche Kolonial-Zeitung* renews the claim of the antimosquito properties of the plant, saying that two or three of those placed on a veranda will drive away all mosquitos from the house. The Department of Agriculture at Washington will, it is said, undertake an investigation to determine the correctness of this claim. In Nigeria the natives, according to the German paper above mentioned, make an extract from the plant that is used in the treatment of malaria in place of quinine, being of equal therapeutic efficacy without any of the disagreeable action of quinine.

**An Imperial Rebuke to an Insanitary City.**—Typhoid fever has been prevailing for some time at Metz, and the municipal authorities, like those of some cities nearer home, did little or nothing to abate the epidemic, although it was shown that the water supply was at fault. Emperor William hear of this, and fearing for his beloved army, telegraphed to Prince Hohenlohe-Langenburg, the stadthalter of Alsace-Lorraine, as follows: "Again, as last year, an epidemic of typhoid fever has broken out among the civil population of Metz, and is threatening the health of the garrison. It has its origin in the bad condition of the springs and conduits, which state of affairs is due solely to the city administration of Metz. According to the report made by the commission which investigated the matter last year, the sanitary conditions prevailing in Metz and its environs deserve the greatest indignation. Such condition can no longer be tolerated. In case of war they would be followed by a catastrophe. I ask your highness to put an end to this state of affairs by the strongest measures." The Burgomaster and the aldermen were highly incensed when this telegram was placarded in the city, but they bestirred themselves nevertheless. The water supply of the city, derived

from the mountain springs at Gorze, was turned off for an entire day and the reservoirs were thoroughly cleaned. Water for animals was brought in carts from other sources, while the inhabitants quenched their thirst with beer and various bottled beverages.

**A Temperance Hospital for Chicago.**—A hospital, to cost $75,000, is to be erected in Chicago, the physicians of which must use no alcohol in their prescriptions. The hospital will be called the Frances E. Willard National Temperance Hospital. The three schools of practice—regular, homœopathic, and eclectic—will be represented on the medical staff.

**Exhibitions of Hypnotism Forbidden.**—The Prussian Minister of the Interior, in Berlin, has reissued the old decree forbidding public exhibitions of hypnotism on the ground that such proceedings are injurious to the subjects hypnotized.

**San Francisco's Chinatown Threatened.**—A report from Washington says that officials of the Public Health and Marine Hospital Service are in consultation with representatives of the business men of San Francisco in regard to a proposition to abolish Chinatown. It is believed that the seeds of plague are kept alive there, and the existence of the quarter thus presents a constant menace to the health of the city. The attempt to stamp out the disease there has been only partly successful, although the most rigid sanitary measures have been practised. Several months ago Mexico and Ecuador declared a quarantine against San Francisco, and the national conference of State board of health officials condemned the hygienic conditions of Chinatown and publicly deplored the danger of a spread of the plague to other States. It is believed by many of those most competent to judge that the situation cannot be permanently improved unless Chinatown is abolished.

**Sanitary Conditions at Ithaca.**—Dr. G. A. Soper, special consulting expert of the State Health Department in connection with the Ithaca typhoid epidemic, has resigned. Dr. Soper is reported as saying that typhoid fever would be stamped out at Ithaca if the local authorities would follow instructions, but they have not even appointed a health board to succeed the men who recently resigned.

**Yellow Fever in Tampico.**—A telegram from Mexico City states that the health authorities of Tampico are taking desperate measures to stamp out the yellow-fever epidemic there. They have just burned 200 residences which have been inhabited by yellow-fever patients. One would judge from this that they had never heard of the experiments of Major Walter Reed and his fellow members of the U. S. Army Commission in Cuba, or of the practical application of their demonstration by Colonal Gorgas in Havana. Dr. Salazar of the American Hospital at Tampico is reported to have died of yellow fever contracted while endeavoring to stay the epidemic.

**A New Cure for Hay-fever.**—Dr. F. R. Stowell of Worcester, Mass., recommends, in an article in the *New York Medical Journal and Philadelphia Medical Journal Consolidated*, the wearing of colored glasses for the relief of hay-fever. There is no question that this will afford some amelioration of the symptoms, but it is not a very novel expedient, for thousands of hay-fever sufferers always wear smoked glasses when out of doors in the sunlight. Their curative action is not very apparent at night, however.

**The Crusade against Tuberculosis.**—It is stated in the *British Medical Journal* that Signor Pietro Cartoni, a wealthy Italian landowner, who has lost two beloved children from consumption, has offered 1,000,000 lire for the erection, outside the walls of Rome, and the partial endowment of a great sanatorium for consumptives. Signor Cartoni has further announced his intention of bequeathing everything he possesses to further the prevention of consumption.

**Obituary Notes.**—Dr. Henry De Haven Cameron late Surgeon of Troop C, N. G. S. N. Y., died of pulmonary tuberculosis in Pony, Mont., on September 4. He was born in Brooklyn thirty-seven years ago and was a graduate of the College of Physicians and Surgeons, New York, in the class of 1889. For a time he was an interne in the New York and Chambers street Hospitals, and then was attached to the Methodist Episcopal Hospital in Brooklyn. He was one of the organizers of Troop C, in 1896, and was first appointed assistant surgeon. He went with Troop C to Porto Rico and performed the duties of surgeon during that campaign. When the troop was mustered out of the United States service he was promoted to be surgeon.

Dr. Joseph Schnetter died recently at Harrenalb, in the Black Forest of Würtemberg, Germany. Dr. Schnetter was one of the founders of the German Hospital and Dispensary of New York, and for forty years was an active practising physician in this city. He was eighty-two years of age. He was born at Gerolzhoven, Bavaria, and was graduated from the University of Wurzburg. He came to America in 1849, and settled in New York, where he soon became connected with many charitable institutions, among them being the German Hospital and Dispensary. In 1889 illness caused him to give up his practice.

Dr. William C. Barrett, dean of the Dental Department of the University of Buffalo, died recently at Nauheim, where he had gone for treatment of cardiac disease from which he had suffered for about a year. He was a graduate of the Medical Department of the University of Buffalo, in the class of 1880, and was a member of the American Medical Association, a former president of the Dental Society of the State of New York and a member of the American Microscopical Society.

Dr. Charles F. W. Myers, for thirty years a practising physician in Paterson, died in that city on September 1 from apoplexy. Dr. Meyers was a graduate of the Medical Department of Columbia University in 1874. He was a member of the Order of Military Surgeons of the United States, and was also on the brigade staff of New Jersey. He was invariably selected as grand marshal of the Republican Presidential parades in Paterson.

---

**Treatment of Mammary Cancer.**—H. N. Chapman holds that all cases of mammary cancer should first be submitted to the *x*-ray, not for the treatment of the disease *per se*, but that the axillary glands may be put into as perfect a condition as possible, and when this has been done, the cancerous mass in the breast should be removed with the knife, but the axillary glands scrupuiously preserved as a defensive barrier. After the wound has healed the glands and breast should be again submitted to the *x*-rays. This conclusion has been arrived at after *x*-ray treatment and observation of four cases operated on by three of our leading surgeons. The axillary glands being removed in each case, and in each case the final result being disastrous. It is well worth while for this method to be tried, because usually the delay will not mean any serious consequences to the patient, and under the present method of operating first and using the *x*-rays afterward the results are extremely humilating.—*St. Louis Courier of Medicine.*

## OUR LONDON LETTER.

(From Our Special Correspondent.)

LORD SALISBURY'S ILLNESS—IRISH MEDICAL MATTERS IN PARLIAMENT—ALCOHOL—NOTES—OBITUARY.

LONDON, August 21, 1903.

LORD SALISBURY'S illness has been the topic of the week. As I write he seems to be *in extremis*. Last night his condition was admitted to be hopeless. At one moment it was thought he had breathed his last, but to the surprise of his watching relatives he rallied again. This attack is one of those which are apt to occur in the course of Bright's disease when the circulation often seems about to fail. Two or three days ago the distinguished patient seemed as if he might once more pass through the crisis of feeble circulation and nerve prostration. But his seventy-three years of strenuous work must naturally be reckoned with, and any of such intercurrent attacks in the course of a chronic enfeebling disease must be dangerous and likely to prove fatal.

Irish medical grievances managed to secure some notice in the House of Commons before the prorogation. Thus, in reply to Dr. E. C. Thompson, M.P., for N. Monaghan, who asked why no notice had been taken of the remonstrances of the medical officers, the chief secretary had to promise that any report the poor law medical officers might make in writing as to their alleged grievances should be considered. Mr. Wyndham also stated in reply to the same member that every application for increase of salary receives the careful consideration of the Local Government Board, and in case of refusal to sanction the increase the reasons are communicated to the guardians concerned. Nevertheless, Dr. Thompson evidently did not regard the statement as satisfactory, for he had referred to several recent instances in which the Government Board refused to sanction increases granted to dispensary officers by the local authorities concerned.

Dr. Thompson asked further why Dr. McCarthy, who lately resigned a temporary appointment, had been threatened with an inquiry as to the cause of his resignation and told that if not satisfactory he would be prohibited from future employment. Mr. Wyndham said Dr. McCarthy refused to enter upon the duties of the office after the approval of the Local Government Board had been obtained, and the guardians were accordingly directed to call upon him to do so, and, in the event of continued refusal, an inquiry would be held with a view to his removal by sealed order. From this reply it is plain that Dr. Thompson's question was justified and that the Local Government Board is addicted to very despotic methods. Dr. Thompson afterward invited attention to a circular respecting consultations on members of the constabulary when the chief secretary said the rule in no way prevented sick members of the force from employing medical men of their own choice, but only the appointed officers could be paid out of public funds.

It would be remarkable if many complaints could be made from Ireland without the introduction of sectarian differences. So it was not surprising that on the vote for the Local Government Board an honorable member took occasion to state the case of the nuns who formerly nursed the Granard Union Hospital, but who had been replaced by lay nurses at great expense to the ratepayers. Friction, he declared, was brought about by the medical officer's adverse reports on the work of the nuns. These latter bore with such insults until their position became intolerable. An inspector was sent down and patched up a peace, and the Local Government Board was to blame for not adhering to that arrangement and not censuring those who ought to be censured. The bishop, finding there was no redress for his nuns, withdrew them. Mr. Wyndham said no reflection was cast upon the nuns, whose services were most acceptable, but they did not care to perform, and ought not to be asked to perform, some hospital duties, and, therefore, it was essential they should have the assistance of trained nurses. Dr. Kenny had expressed regret for the manner in which some of his dissatisfaction had been stated, but it was necessary to point out defects, and there was no reason why the nuns should not resume their work.

Mr. T. M. Healy treated the House to his view of medical questions. His sympathy, he said, was altogether with the ratepayers. Every fad of a medical man—the discovery of a new disease or a new cure—was sure to be supported by the Irish Government Board. He did not read of those diseases and cures either in Shakespeare or the Bible, though people in those days were as healthy as those of to-day with a government board to look after them. If medical fads were to be carried out let it be at the cost of Imperial faddists, not local ratepayers. In a small union hospital they could not expect the environment of Guys or St. Thomas's Hospital.

All this parliamentary talk arising from a difference between nuns and lay nurses is very Irish. Sectarian prejudices penetrate where you might not expect them. A councillor of one of the royal colleges once confided to me that he could not trust a brother councillor to vote as he had promised, and when I asked why he simply said "sure, I wouldn't believe one of his faith."

Irish poor law medical officers have at present nothing to thank Mr. Wyndham for. On a previous occasion, questioned as to their grievances and the difficulty of filling vacancies, he admitted they had very hard work for salaries which were "not high," but added that "their claims would be more deserving of recognition if they waited for the report of the vice-regal commission" instead of adopting the plan of the Irish Medical Association, which is to refuse dispensary appointments at less than £200 per annum. Yet, not long ago, he said these very grievances were beyond the scope of that commission. I hope his great parliamentary success has not impaired his memory. Perhaps he has accepted without thought the answers prepared for him by the official staff—a practice likely to lead to contradictory statements. While devoting millions to pacify political agitators he might spare a few hundreds for the starved medical service.

Dr. Roberts has been taken to task for his rather loose quotation of the international manifesto on alcohol. In his address he referred to the signatories for "some of whom" he professed the greatest respect as persons "who absolutely and entirely object to the use of alcohol in any circumstances." Now the manifesto in question refers only to alcohol as a beverage and says nothing about its use as a medicine. We have here, as you know, a medical temperance association, but its members do not absolutely abjure the use of alcohol as a drug. It would have been more prudent of Dr. Roberts to verify his reference before making his criticism.

This subject of alcohol came up on other occasions at Swansea. In the Section on Psychological Medicine there was a notable discussion about its relation to mental disease opened by Dr. Hyslop, Medical Superintendent of Bethlem Hospital. He held that it did more harm than good in the body, and that in weakly, especially neurotic persons, it might be compared to a loan at heavy interest. It produced a deceptive feeling of well-being, but lowered mental capacity and energy while producing confusion of ideas. The muscular overaction under its influence was the result of stimulation of the motor areas and diminished power of the inhibitory cortical centers. It increased the exudation of lymph and leucocytes from the cerebral vessels into the surrounding tissues. Referring to the morbid changes induced in the brain, he traced their relation with the clinical and psychological symptoms of alcoholism. He thought that alcohol *per se* did not cause general paralysis of the insane.

Dr. Archdall Reid followed with a paper on "Human Evolution in Relation to Alcohol." He laid down a series of sixteen propositions which he considered undeniable, more or less, for he had to admit that some of them would be disputed, while the conclusion to which they led him had been strongly denied. He has for a long time advocated views which are more or less in opposition to the opinions generally entertained, particularly as to the effect of alcohol on the race. He has no fear of its causing degeneration or extinction of races, for he holds that those which have indulged in it over the longest periods are now the most temperate people on earth, and in support of this instances Jews, Greeks, Italians, and other Southern Europeans as less drunken than the peoples of Northern Europe, while some savages with little or no experience of the poison are the most drunken of all. He repudiates the prevalent opinion that parental intemperance affects offspring subsequently born, and says that if true it would be an exception to an apparently universal law. The statistics which have been published in support of the general view he puts aside as compiled by those who believe they are supporting an indisputable fact—a large part of them further compiled before exact observations on heredity had been made.

There was quite a long discussion on these two papers, in which, as you will suppose, many of the speakers criticised the propositions put forth by Dr. Reid, more especially those which directly contravene prevalent opinions.

The bioscope is being shown extensively at places of entertainment. At one the circulation in a frog's foot is being shown on the screen. The mites in a piece of cheese are exhibited crawling about magnified to look like small crabs. The sap coursing through the veins of the water weed. The dart of a chameleon's tongue and other living pictures—the most attractive being perhaps the work of the bees in a hive.

Dr. A. Castellani of the Uganda Malaria Commission and who found the organism in the spinal fluid of patients with sleeping sickness—a discovery which is receiving more attention just now—has been appointed by the Government of Ceylon to a professorship of pathology and bacteriology.

Smallpox is diminishing in the north and also at Cambridge.

Dr. Ivor Murray, who died on the 24th ult., aged seventy nine years, had seen much practice in China, where he built a hospital in 1852. On the outbreak of the Crimean War he sailed for Sebastopol and was appointed to the Balaclava Hospital. Later he served as Colonial Surgeon at Hongkong. From 1875 to 1900 he practised at Scarborough. On retiring he took up his residence in London, where he died.

Dr. Wm. A. Henderson, who also served in China for more than twenty years, died on the 28th ult., aged fifty-seven years, at Florence, to which he had retired in broken health. He had made a special study of psilosis, from which he had himself suffered.

Dr. Meller, formerly M.O.H. for Carisbrooke, died on the 1st inst., aged eighty-three years.

Dr. Weaver, who also died on the 1st inst., aged seventy-one years, had served in the navy during the Crimean War. Subsequently he had been M.O.H. for Longton, where he practised for some twenty years and afterward retired to Southport, where his son is now M.O.H.

A sad accident was the cause of death of Dr. J. Riley Greenway at the Tunbridge Wells Hospital. He was waiting at the station and as a slow train passed was seen to fall backward between that and the platform. He was greatly injured; the skull being fractured was the cause of death. He had been in ill health for some time and suffered from occasional giddiness, which was doubtless the cause of his falling. He was sixty-seven years of age and had retired for some time.

## LETTER FROM CONSTANTINOPLE.

(From Our Special Correspondent.)

DECREASING DEATH RATE—THE AMERICAN MEDICAL SCHOOL AT BEYROUT—A NEW MEDICAL SCHOOL AT DAMASCUS—LEPROSY—IRREGULAR QUARANTINE AGAINST PLAGUE—THE HAMADIEH HOSPITAL—THE THERMAL SPRINGS OF ASIATIC TURKEY.

CONSTANTINOPLE, July 31, 1903.

THIS season has been remarkable for its variations of temperature; but that these variations have been within healthy limits may be inferred from the statistics of diseases and deaths, which have been, so far, under the average.

The prevailing malady of the early summer season has been German measles, characterized by glandular complications. Some cases of smallpox, which disease, for practical purposes, may be considered a mildly endemic condition; and a slight increase of typhoid cases.

The scares of cholera and plague during the past three years gave an undue stimulus to sanitation; undue in the sense that the measures adopted to keep out these plagues had little relation to the external conditions of the population. The external conditions of quarantine were, to a certain degree, favorably reflected internally, and doubtless produced good results, as in spite of much accumulated dirt and municipal neglect of the various "Imperial Iradés," the death rate is gradually diminishing.

It may be feared that in proportion to the diminution of disease the municipal health authorities may diminish their energies. The Imperial Society of Medicine, after an ordinary session, is now *en vacance* until autumn. Doctors and patients who can afford the luxury have betaken themselves to the various summer resorts of the Bosphorus and islands, or to the baths of Broussa and Yalova.

The American Faculty of Medicine of Beyrout has succeeded in obtaining a like privilege to that of the French Faculty, viz., that instead of the students being obliged to come to Constantinople for their graduation examination, representatives of the Imperial Faculty of Medicine will join the American examining body at Beyrout. The examiners for the first examination were Drs. Mahmuud Hakki Pacha, Hairaddin Pacha, and Rifaat Husammedin Bey, who have finished their task and returned to the capital. They report favorably on the results of their labors.

Another faculty of medicine has been ordered by imperial "iradé" to be created at Damascus. The "iradé" grants a credit of one million piastres for the building of the structures and another million for other expenses of the faculty. Meanwhile a large "conak" will be hired and a sum of twenty thousand piastres yearly is allowed for this purpose. The taxes on slaughter houses are assigned to the support of this faculty, as follows: oxen, 5 pias; calves, 3 pias; sheep, 1 pia; goats, 30 paras, and lambs, 8 paras. A further announcement is made that a concours will take place at the Imperial School of Medicine for the three chairs at the Damascus Faculty: (1) Physics, 1,200 pias per month; (2) Geology, 300 pias; (3) Chemistry, 1,200 pias. The Professor of Physics will also take the geological course and exercise the functions of Director of Studies, with a supplementary pay of 1,000 pias per month. All this sounds very good and nice!

An association has been formed against consumption, which also sounds good and nice!

Dr. Zambaco Pacha, who is a well-known and distinguished writer and authority on leprosy, is a strong non-contagionist. Some six years ago, when the question was discussed at the medical society, Dr. Zambaco asked that a commission should be named by the Imperial School of Medicine for the study of the transmission of leprosy at Constantinople. The commission, it is said, after numerous researches, was not able to advance a single fact in favor of contagion. The commission, however, not having yet presented its official report, the learned Pacha, truly considering the question of importance to science and humanity, has again brought forward the subject. Zambaco Pacha's opinions are too well known to need repetition here, and are entitled to careful consideration, as few have had more opportunities of studying the disease in different countries of the East and Europe, and among varied races. He now challenges the opinions and so-called proofs of the contagionists in a series of questions, he, himself, stating: "*Quant à moi, je répète partout et toujours; je ne cesse de m'enquérir méticuleusement auprès des nombreux lépreux qui continuent à venir à moi et que j'adresse aussi à d'autres confrères avec prière de les étudier, et je n'ai jamais eu la chance de tomber sur un examp le de contagion qui me fît plier devant l'éclatante vérité.*"

This clear statement of Zambaco Pacha is apparently intended to apply to Turkey, as he admits that, possibly, leprosy does not everywhere comport itself in the same way. Although a small leper house exists near Scutari, on the Asiatic side of the Bosphorus, it appears to have only a few stationary families from the interior provinces, who are not much restricted. But as Dr. Zambaco observes, it is quite notorious that Constantinople, as other capitals, contains numerous lepers living in their families in the midst of society, circulating everywhere and following various trades and professions; fish and fruit merchants, boatmen, silk merchants, domestics, even school teachers, without prophylactic measures. In the winter session of the medical society an interesting and useful discussion on the subject may be forthcoming should the medical body of Constantinople respond to Dr. Zambaco's invitation in the sense he asks.

Quarantine against Syria and Egypt is still in force—being somewhat spasmodically relaxed or increased, according as an extra case of cholera or plague occurs. As these conditions of quarantine may continue in indefinitely, those interested are asking if it would not be well to recognize that plague is endemic in these places, and establish a reasonable and steady period of quarantine observation and precaution in place of the shifting and changing proceedings now practised which satisfies none and disturbs all? At the present time it is somewhat more stringent, as the reports from Syria state an increase of cholera at Devi Ali, four hours from Damascus, though there is, as yet, little indication, if any, of the seacoast villages of Syria being infected.

His Majesty, the Sultan, has decided that four new pavilions shall be constructed as the "Hamadieh" hospital for electrotherapeutic purposes. What is the "Hamadieh" Hospital? It is the show hospital of Constantinople, and a first rate show it is in a city where nationalities, great and small, "go in" for hospitals, which for size and cost are out of proportion to the requirements of their communities, *i. e.* their poor.

Of thermal springs Asiatic Turkey possesses many, the most celebrated are those of Broussa, Courej-Yalova and Mitylene. The two former enjoy a high reputation, and each has a past history. They, also, are within easy distance of the capital. The springs of Courej-Yalova date from antiquity, when they enjoyed high reputations for therapeutical value, and, old chroniclers record, were the seat of an oracle. Several tables in marble have been found near the principle sources of the baths, *ex votos*, dedicated by the sick cured of their diseases and an inscription in the Doric dialect containing the regulations for the sacrifices offered through the intermediation of the Asklapithytai or the priests of Æsculapius. It is ascertained from these monuments that the thermal springs were under the special protection of Hercules, and that there was a sanctuary of Æsculapius and of three nymphs (a nympheon). To this day there exists a little town

in the locality "Eregli" (*i.e.* Hercules) associated with a legend of the Argonauts.

These monuments and legends, dating from Greek and Roman sources, prove that these thermal springs enjoyed a well-established reputation. With the establishment of the Empire at Byzantium by Constantina the Great the old Pagan gods disappeared, the oracle ceased to work, and the *ex-votos* became sunk under ground near the springs. Constantine himself had recourse toward the end of his life to these baths, and it is gathered from contemporaneous sources that these hot springs (of Pythiæ) occupied an important hygienic place, as in 529 A.D. the Empress Theodora, wife of Justinian the First, went there accompanied by a suite of 4,000 persons. This alone will give an idea of the importance of the springs.

The decadence of these baths (of Pythia?) began under the Macedonian dynasty (ninth and tenth century). The provinces became battle-fields and were devastated for the next three centuries. Baths then became too much of a luxury, and those of Yalova disappeared from the history of the times until lately revived. The late Dr. Julius Millingen, a physician of reputation in the service of the Ottoman Government, found the "Valida Sultana" (*i e.* mother of the Sultan) suffering from some malady as history attributed to the Empress Helena, who apparently had undergone the "cure." Dr. Millingen sought for and found, the forgotten hot springs, and advised the Sultana to take the treatment. She recovered her health. Yalova then came into vogue more or less, and became a fashionable watering place for the Turks of Constantinople and the surrounding districts. Thus far the historical record elucidated by various local authorities.

At the present time Yalova is likely to become a real health resort for all classes, inasmuch as the baths and estates attached to them are now the property of the Civil list, have been placed under the skilled management of M. and Mme. Brauzeau. These springs are about four hours distance from Constantinople—by steamer and carriage. The waters have a temperature of 64.5 C. to 68 C., are sulphurous, and are compared favorably with well-known spas of Europe, as Teplitz (Bohemia), Gastein (Austria), Plombières (France), and Wildbad (Wurtemberg). The people of the country state that the temperature of the waters is the same at all times of the year or seasons.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

SURRA—MODE OF INFECTION WITH THE TRYPANOSOME—SURRA IN RATS AND OTHER ANIMALS—SYMPTOMS OF SURRA — RINDERPEST — PREVENTIVE INOCULATION AGAINST RINDERPEST—CATTLE PEST—A CATTLE QUARANTINE STATION.

MANILA, July 18, 1903.

MUCH of the attention of the Board of Health is now being given to the question of animal diseases. The Bureau of Government Laboratories for the Philippines has just issued a bulletin relative to the occurrence of trypanosomiasis, or "surra," in the horses of the islands. The bulletin takes the form of a preliminary report on the subject written by Drs. W. E. Musgrave and N. E. Williamson, who has been engaged in work on surra for some months. The disease was first recognized as occurring in the Philippine Islands late in 1901 by Smith and Kinyoun, and described by them at that time. Since then several papers have appeared on the subject. Drs. Musgrave and Williamson are inclined to the belief that surra had not previously existed in the Philippines prior to May or June, 1901, nor that it was imported from China, as it is not known to exist in that country. From a study of the animals brought to the islands at about that time, they come to the conclusion that the infection was probably introduced by the wild animals brought with a circus from Singapore, though the disease first appeared among a lot of race horses imported from Australia. From these, the spread of disease was rapid. While no record of the native stock killed by the disease is, of course, obtainable, the records of the army show that in the two years, 1901–1902, there died from diseases in the military service, largely from surra, 5,787 public animals. The writers estimate that the introduction of surra into the islands has resulted in a money loss of not less than $2,000,000.

The bulletin states that so far as direct evidence goes, surra is a wound disease, and the infectious agent must be brought into contact with a wounded surface of the skin or mucous membrane. This belief has long been entertained elsewhere, and has been confirmed by the work here. Biting flies are chiefly the carriers of the infection, but do not seem to be able to carry the infection more than two days after feeding on infected blood. This mode of transmittal seems to be mechanical and the fly does not act as the intermediate host of the parasite. All biting flies and insects are dangerous, and the common house fly, which does not bite, may carry the parasite to an abrasion or wound on an uninfected animal. A number of rats taken in Manila have been found to harbor the surra parasite, and may, very possibly transmit the disease to horses through the agency of infected fleas, while there is a common belief that the disease is carried by food and water, yet the observers have never been able to induce it by feeding hay contaminated with surra blood, unless the mucosa of the mouth were wounded, in which case the disease developed promptly. Surra may be mechanically transmitted by the use of bits, harness, currycombs, etc., from infected animals.

The writers state that certain animals may harbor the surra parasite for long periods and thus maintain the infection, particularly certain wild animals, camels and bovines. Horses and mules die within a few days or weeks aftre being infected, and so far as known, no case of recovery in these animals is recorded. The disease is uniformly fatal among them, and for this reason the writers claim that there is nothing to gain and much to lose by postponing the destruction of such infected animals.

They state that the rats, which are already infected, and the wild animals of the islands, which soon will be infected, if they are not already so, must be taken into consideration in any measures looking to stamping out surra, and the problem of getting rid of the disease is thus made more difficult. The experiments of the writers show that the surra parasite quickly dies on grass, and hay and in water, and that the disease occurs as frequently among American horses fed of food brought from the United States as in the grass-fed Filipino ponies. While the disease occurs most commonly in marshy, damp districts, an infected animal taken to a new place becomes a focus for the spread of the disease if biting flies are present, whether the locality is marshy or dry. The biting flies, however, seem largely to require moisture for their development, and are much more common during the rainy season. The writers state their belief that if it were possible to destroy every infected animal and protect the remaining ones from infected flies for forty-eight hours, there would never be another case of surra in the country unless the infection was again introduced from outside.

The early symptoms of surra are thirst, dejection, and a remittent fever. There is anæmia, shown by pallor of the mucous membranes, which take on a pearly white or yellowish tinge. There is a catarrhal discharge from the nose and eyes, with swelling of the lymphatic glands about the jaws. Œdema is a later symptom, beginning in the hind legs or sheath and extending along the belly. The disease frequently ends by paralysis of the hind parts. It is impossible to make a diagnosis of the disease in its early stages, except by the use of the microscope.

To prevent the introduction and spread of the disease, the writers urge the exclusion of all animals coming from an infected port, or, at least, an extended quarantine. Circus animals and menageries should be prohibited entrance. Early diagnosis is essential, and an animal found to be affected should be at once killed and sent to the crematory in a fly-proof wagon, or, if this is not practicable, the body should be protected against flies by a coating of earth or by being covered with a mosquito bar for twenty-four hours. Stables should be kept dark and thoroughly clean, and occasionally washed down with some strong-smelling disinfectant. In the surra season all cases of fever should be at once isolated pending diagnosis. The allowing of horses to congregate in large numbers, as at public cab stands, should be prevented.

Rinderpest is also causing much destruction among the bovines, and the work of protective inoculation against this disease of the thousands of carabao being purchased by the Philippine Government to restock these depleted islands is now being vigorously carried on at Shanghai. This disease has detroyed about four-fifths of the carabao formerly in the islands, and the present work of restocking would be unavailing unless the animals imported had been previously immunized against rinderpest. The carabao are being supplied by private contractors to the government, but the work of preparation of serum and inoculation is carried on under the charge of a government expert.

The method of inoculation is simple. After the animal is placed in bamboo stocks to prevent resistance, 1 c.c. of virulent blood from a diseased animal and 30 c.c. of serum from an immune animal are injected into the subcutaneous tissue of the chest well behind the forelegs. The battle for supremacy begins in a few minutes, the ultimate outcome depending to a great extent on the vital resistance of the animal, which soon sickens with a modified attack of rinderpest. In the Shanghai yards about 10 to 15 per cent. have succumbed after inoculation, which is a pro-

portion about twice as great as obtains among animals inoculated in the Philippines, and this loss the contractors have had to take into account in making their bids. Recently they have made arrangements to have the serum sent from here. The Shanghai yards are divided into a number of pens, from one to another, of which the cattle are moved according to the stage of the disease. Those presenting a severe form of rinderpest are placed in a covered yard, holding as many as 500 head. Great pains are taken to destroy all refuse by fire, keep the premises properly disinfected and in a state of scrupulous cleanliness. As the animals convalesce, they are removed to other yards, according to the degree of recovery, and finally, after they recover their appetite and begin to take on the flesh lost during the two weeks required for immunization, they are ready for shipment to the Philippines.

The government authorities hope that through careful inoculation, perseverance, and proper selection a breed of carabao may ultimately be developed which may possess a relative resistance to rinderpest, and thus do away with a disease which perhaps more than any other one thing stands in the way of the commercial and industrial advancement of the islands.

The first method of preventive inoculation against rinderpest used here was that of injecting the bile of an animal dead with rinderpest, 10 c. c. of such bile mixed with 20 c.c. of glycerin being used for this injection. This method, however, while of some value, nevertheless presented an unduly high mortality. The immunizing serum, which is now employed with such excellent results, is made by injecting the animal with 1 c.c. of virulent blood from a sick animal and 30 c.c. of immunizing serum. After the animal has recovered from the disease so produced and has regained a normal temperature, 20 c.c. of virulent blood are injected, which induces another febrile movement. After the temperature has returned to normal a still larger injection of virulent blood is made, until the animal is able to receive an injection of 1,500 c.c. of virulent blood without rise of temperature. It is then ready for bleeding in the production of immunizing serum, and will furnish prophylactic serum sufficient for the immunization of some eighty animals. In the preparation of this serum it is necessary to have a constant supply of animals sick with rinderpest from which virulent blood can be obtained, and a succession of susceptible animals for its production.

The Board of Health has lately drafted a comprehensive law for the prevention of rinderpest in these islands, the provisions of which, if properly carried out, should ultimately exterminate the disease in the archipelago. This proposed law is now before the commission for its legislative action and will undoubtedly meet with its approval.

As if the presence of rinderpest and surra were not enough of an industrial calamity, a number of the carabao already imported by the government from Shanghai have developed "cattle pest," which in its pathological changes and specific germ closely resembles those of bubonic plague. The microorganism is, however, somewhat larger. The disease has appeared here in a variety of forms, but is apparently identical with the uniformly fatal "cattle septicæmia" which has from time to time occurred in parts of the United States, notably in Minnesota. The disease has heretofore been unknown in these islands, and fortunately the cases were detected before the animals had been removed from quarantine, so that it is not likely that a foothold has been gained here. All the carabao affected have died, and all those brought into contact with the sick animals have contracted the disease. The symptoms are slight fever, hemorrhages into all the organs, paralysis of the hindquarters, and in some cases sudden death in an apparently healthy animal. A number of the cases here have presented a septicæmic form of a more chronic nature, characterized by the development of numerous abscesses occurring particularly in the flanks and about the joints. After the onset of the disease, the animals appear for a few days to be on the road to recovery, but a subsequent relapse carries them off after an illness of a week or ten days. The method of combating the disease, so far, has been to stake out all animals so that there can be no communication between them. As soon as the disease develops, the animal is killed and the body cremated. The site where the animal was tied is then covered with hay wet with kerosene oil, and the whole burned, and the ground is then drenched with strong carbolic-acid solution. Wallows used for mud baths by carabao developing the disease are disinfected with carbolic acid, and their further use abandoned. The health authorities deserve much credit for so promptly recognizing the nature of this new disease, and taking the proper preventive measures before it had a chance to spread. So far as known, treatment is unavailing in this disease, and to have had it added to the other animal diseases here would have been a severe blow to the industries of the islands.

In view of the early importation of thousands of carabao, many of whom are liable to have this or another infectious disease, the immediate establishment of a proper cattle quarantine station is urgently required. A site has already been selected, and pending the erection of the necessary buildings and fences, the cattle will be quarantined under the guard of native constabulary. The Board of Health is alive to the necessity for thorough and prompt action, and with a quarantine station here and one at the point of embarkation in Shanghai the immunization of carabao against rinderpest, the disinfection of every ship bringing cattle, and the broadcast dissemination of knowledge relative to the nature and measures of prevention against surra, it seems to have done about all in its power in the matter of preventing disease in live stock.

**The Resistance of Tissues as a Factor in the Manual Reduction of Congenital Hip Dislocation.**—E. H. Bradford presents a study of the obstacles to the reduction of a congenitally luxated hip, the chief of which are in the soft parts, and summarizes the results of this study as follows: (1) The resistance offered by the capsule to the correction of congenitally dislocated hips is not more important than that offered by the muscles. (2) The chief resistance to forcible abduction is from the strong tendon of the abductor magnus. (3) The resistance to pulling down the head comes from the hamstring group and the long tendon of the abductor magnus and iliotibial band. (4) These resistant tissues can be overcome by small incisions at a distance from the hip. (5) In the lighter cases manual manipulative reduction is sufficient. (6) In resistant cases, mechanical force which pulls upon and abducts the limb, arranged so as to also directly act upon the capsule, is of assistance. (7) Where the tendon of the abductor magnus is so strong that an immoderate amount of force is needed in stretching, it would seem advisable to divide the chief resisting tissues rather than to incur the danger of severely bruising the tissues by the force used. The division of the tendon can be done either before the operation of forcible correction or at the same time.

*Journal of the American Medical Association, Sept. 5, 1903.*

**Neuroglia Tissue and Ependymal Epithelium in Teratoid Tumors.**—Henry A. Christian says that neuroglia tissue is a common constituent of teratoid tumors, its structure in them being very varied, simulating many known forms. Neuroglia is more intimately associated with mesoblastic tissues in teratoid tumors than elsewhere. In such tumors occur isolated fibers and groups of fibers which stain like neuroglia, but whose nature can not be determined by staining reactions of Mallory, Huber, and Benda, since these methods may stain other than neuroglia fibers. In many cells of these tumors occur small dots or groups of dots which have similar staining reactions to neuroglia fibers, and the presence of these dots in cells, though not absolutely diagnostic, may be considered as evidence in favor of the ependymal origin of the cells in which they occur.

**Hæmoglobinuric Fever.**—Walter Shropshire has obtained reports of cases of blackwater fever from forty-one physicians of southern and eastern Texas and Louisiana, and from a study of the 173 cases reported by them and of 29 cases observed by himself concludes that the affection is of undoubted malarial nature. In proof of this he offers the following: (1) This disease always occurs in persons suffering repeated attacks of malaria (this was so in every case reported). (2) It nearly always follows one or more mild paroxysms of malaria at the proper time for its next exacerbation (there was but one exception to this reported). (3) It has all the characteristics of malaria, viz., chill, fever, and sweat. (4) When adequate examination of blood is made, the hæmatozoa of malaria are found. (5) Its habitat, that of most violently malarious districts, is sufficient to establish malaria as a causative agent, if not the only one. The only other cause alleged by a sufficient number of authorities to merit consideration is quinine. As a result of his studies the author finds the evidence against this drug as a causative agent very strong. He summarizes the evidence for and against quinine as follows: Of the physicians reporting, 29.4 per cent. affirm it. When quinine was suspended in treatment, 73.8 per cent. recovered. Distinct recurrences of attacks after the first appearance of blackwater in non-quininized

patients, 9.8 per cent. Per cent. of cases occurring from quinine alone, 0. Per cent. of cases in which quinine was thought to aggravate, 5.9. Of the physicians reporting, 70.59 per cent. deny it. When quinine was administered 83.1 per cent. recovered. Distinct recurrences of attacks after the first appearance of blackwater in quininized patients, 4.4 per cent. Per cent. of cases occurring from malaria without quinine, 15. Per cent. of cases in which quinine was thought not to aggravate, 55.4. Being a believer in the curative and not the causative action of quinine in hæmoglobinuria, the writer urges the administration of quinine in daily doses of 40 grains, administered hypodermically or intravenously, until the next period for an exacerbation is safely passed, and continued in half that dose until the second expected exacerbation is safely passed, when it should be discontinued for three or four days, and repeated in 20 to 30-grain doses every four to six days till five or six weeks have passed without a paroxysm.

*Medical News, September* 5, 1903.

**Puerperal Insanity.**—J. W. Palmer divides puerperal insanity into the conventional classes of (1) insanity of pregnancy, which is usually melancholia; (2) puerperal insanity proper, which comes on in a limited period after delivery and is usually in the form of mania, and (3) insanity of lactation, which is mostly melancholia. The first is the least frequent of all. Under each heading are considered causes, etiology, prognosis, and treatment. The paper is a good consideration of the subject from a clinical standpoint, but offers nothing new.

**Perineal Prostatectomy Without Opening Urethra or Bladder.**—The patient of J. R. Eastman was sixty-nine years old, presenting the usual symptoms of enlarged prostate. The gland was exposed by an inverted Y incision and the capsule split transversely. The gland was removed mostly by being shelled out, but partly by morcellement, and this being accomplished without opening the posterior uretha. It was not deemed safe to permit the bladder contents to escape through the perineal wound, and it was hoped that the obstruction was entirely removed, since by sweeping the convexity of the curve of a large sound across the mucosa of the bladder floor, and following it with the index-finger in the perineal wound, it could readily be determined that the floor of the prostatic urethra and bladder were quite thin. It was subsequently proven, however, that the obstruction was not removed. The residual urine was decreased in amount, but at least three ounces remained. The other symptoms were in nowise improved. After three weeks the perineal wound, which had not yet closed, was re-entered and the posterior urethra opened. On passing the finger through the latter incision, a thin stricture-like obstruction was met at the orifice which raised the bladder outlet at least a half an inch above the level of the bladder floor. The stricture-like obstruction was cut down by galvanocautery division of the urethral floor. This was done with the instrument devised and used by Dr. Wishard of Indianapolis for cauterization of the prostatic collar through a perineal incision. A large perineal drain was left in for ten days. After its removal the wound rapidly closed and dilatation of the posterior was regularly done. Results were most satisfactory.

*New York Medical Journal, September* 5, 1903.

**A Case of Atropine Poisoning.**—C. B. Cortright reports the case of a boy, eight and a half years old, who swallowed two grains of atropine sulphate. When seen twenty-five minutes later, he had a scarlet rash over the face, chest, and abdomen, dilated pupils, very rapid pulse, rapid and deep respiration, dry skin, fibrillary twitching of the skeletal muscles; he was profoundly unconscious; there were slight spasms around mouth and tongue. Morphine sulphate, ¼ gr., was given, and the stomach was washed out with saline infusion at 110° F., until the fluid returned clear. High saline enemata of four pints each, at 110° F., were given every two hours, the amount being gradually diminished, because the enemata were expelled. Two drachms of magnesium sulphate were added to each enema. He was catheterized and given strychnine sulphate $\frac{1}{100}$ of a grain, every three hours, and was surrounded with hot blankets and hot water cans. Iced compresses were applied to the head. The last dose of strychnine was given ten hours after the atropine had been swallowed, and the last saline enema was given fourteen hours after the ingestion of the poison. The boy recovered.

**The Adams-Stokes Syndrome.**—Peter Bassoe reports at length a case of this affection, from a study of which and of other cases recently reported by Luce, he comes to the conclusion that this symptom-complex is not a clinical entity. It may supervene in various diseases involving the heart, vagus nerves, or medulla oblongata, and is especially likely to occur when the upper part of the ventricular septum is diseased. Arteriosclerosis is not essential to its occurrence. Its presence in the case reported, in which there was a localized lesion of the intramedullary portion of the accessory nerve, lends support to the hypothesis that the inhibitory fibers of the heart are derived from this nerve. A lesion of the intraventricular septum may produce bilateral degeneration of the extramedullary cadiac fibers of the vagus nerves. The muscular origin of bradycardia is proved by the fact of the occurrence of slow heart in a case with bilateral vagus degeneration, since then the inhibitory influence of the vagi must be absent. The fundamental feature of the Stokes-Adams syndrome is the bradycardia, for the nervous symptoms vary greatly, according to the degree of susceptibility of the nervous centers to the circulatory disturbances resulting from the bradycardia.

**The Operative Treatment of Tuberculous Glands of the Neck.**—J. G. Sheldon says that his treatment of this condition to-day differs radically from that employed by him a few years ago. Then he was satisfied with curetting in certain cases, and in others with removal of all the palpable glands. Now his operations for tuberculous glands of the neck consist of thorough cleaning out of the diseased areas. The glands, fat, infected fascia, and, in fact, everything except important vessels and nerves are removed. If only a portion of one triangle is invaded by the disease, the entire space is thoroughly dissected; if the region anterior to the sternocleidomastoid is involved, a dissection is made from the styloid process to the sternum; if the posterior triangle is diseased, a dissection is made from the mastoid to the subclavian vein. His experience has been that usually a dissection of the entire region of the neck on the affected side has been necessary to secure a permanent result. He has had three cases in which he deemed it advisable to dissect the submaxillary triangle only; the result was satisfactory in each case. He has had three or four other cases in which he thought dissection of the submaxillary triangle with removal of one or two enlarged glands in the region of the internal jugular was sufficient; recurrences invariably followed these incomplete operations.

*American Medicine, September* 5, 1903.

**The Abuse of Inflation and Massage of the Middle Ear.**—Emil Amberg utters a caution against the indiscriminate employment of inflation and massage in otitis media. Three suggestions are made as to treatment of non-inflammatory processes in this region: (1) The use of the Siegle pneumatic ear speculum, especially for diagnostic purposes, is an absolute necessity. (2) Treatment should continuously be controlled by hearing tests. (3) Local treatment of an injurious nature should absolutely be desisted from. In cases in which the membrane is relaxed from ankylosis of the ossicles, the use of the pressure sound is indicated. Amberg thinks that there may be a possibility that massage carries with it a certain danger to hearing, by causing a flabby membrane and, perhaps, loosening the joints between the ossicles.

**The Significance of the Convulsion in Idiopathic Epilepsy.**—J. W. Whitney advances the theory that the convulsive seizure in epilepsy is a physiological process designed for the patient's relief, and that when adequate it rescues him from the overwhelming effects of an intoxicative that might otherwise result in death. It is analogous to vomiting as an effort of nature to relieve gastric irritation. According to this view, epilepsy is due to an autointoxication which becomes more and more intense and concentrated and finally bursts forth in a muscular explosion, *i. e.* the convulsion which is therefore a sort of safety valve. The explosive point is determined by the pathological condition of the cell, and the latter varies with the disease involvement present in the different sections of the motor area. On this theory, efforts to throttle the convulsion are harmful rather than beneficial. Bromides have often caused dementia and may provoke the very intoxication we strive to avoid. We have used the bromides, says the author, to beat the brain into insensibility. This is the epileptic cycle. A poison which irritates the vasomotor center; complete vasomotor spasm, cerebral nonoxygenation; unconsciousness: then comes universal convulsion; further increase of carbon dioxide; relaxation of vasomotor spasm; neutralization of poison; return to consciousness, and, after a period of rest, a feeling of bodily comfort unknown before the attack. This is the cycle when unhampered and unobstructed by vicious and irrational treatment.

*The Lancet, August* 29, 1903.

**Intussusception of the Vermiform Appendix.**—F. P. Connor describes the case of a boy nine years old, who a month before had received a blow on the abdomen. Symp-

toms of peritoneal trouble developed but gradually passed off. Over a month later they reappeared, and a diagnosis of intussusception was made. This was discovered, on abdominal incision, lying obliquely at the level of the umbilicus. Its greater bulk, consisting of ileum, was easily reduced till the cæcum was reached. A remaining mass was found to be a completely invaginated appendix, which was removed with the caput cæci. The bowels were opened by enema on the fourth day, and perfect recovery ensued. So far as the author knows, this is the first recorded case in which the appendix itself has formed the apex of the intussusception.

**A Case of Automatic Wandering Lasting Five Days.**—The patient of W. S. Colman was a temperate man, aged thirty-seven years and of a definite family history of neurotic affections. He had had one prolonged and several short attacks of the nature described. During the one under discussion he wandered away from home, and at the end of five and a half days found himself in a strange town in which he had never been before. His clothes were muddy, as if he had slept by the roadside, and his general condition suggested that he had been steadily tramping. Examination revealed no evidence of organic nervous disease, and no history of *petit mal*. He was in good health and anxious to resume his work, the nature of which is not stated. Several similar cases are referred to by the author, who calls attention to their manifest medicolegal importance. He notes that automatism after actual epileptic fits is well recognized by medical men, and even magistrates are less skeptical than they were about its possibility. It is well that it should be known that exactly similar attacks may occur not only after epileptic attacks, but even in those who have never suffered from actual fits. But it may be extremely difficult in any given case to decide whether a person is truthful in professing to be entirely oblivious of past actions on his part. He advises that such patients should always carry with them a card indicating their liability to such attacks and giving the names of two responsible persons who could be communicated with in the event of their being found wandering or getting into the hands of the police.

**A Note on the Etiology of Yellow Fever.**—The author, J. B. Tombleson, contracted the disease from a mosquito bite. He had a mild febrile attack lasting only two or three days, of the nature of which he was ignorant. Blood tests were made, and contained, among other germs, a short oval bacillus, almost coccoid in form. Some two weeks later he had a similar, though less severe, attack with similar findings in the blood. A month later he attended a fatal case of undoubted yellow fever, from the blood of which he isolated a bacillus similar in appearance to the one above described, and this time this special bacillus alone was found. Inoculation of cultures of the latter into various kinds of animals was followed by fatal attacks exactly resembling those of yellow fever. At the end of another month he himself was taken down with what turned out to be a modified attack of the same disease. In his blood the same bacillus was again found, the culture reactions of which are stated in full. Hence he resumes that the bacillus was found in his blood in two small febrile attacks; it was found in the blood of a typical fatal case of yellow fever; it was injected into and found capable of producing disease in a wild dog; it was injected into a monkey, producing a disease having the symptoms and typical ending of yellow fever; and it was found after death in the blood and tissues of the monkey in pure culture. It was inhaled by himself, and he, after an interval of eight or nine days, contracted yellow fever, cut short, as he believes, by the comparative immunity produced by the two mild attacks previously mentioned; his blood serum after recovery clumped a motile culture of the bacillus, and his blood, taken at the outset of the disease, contained the bacillus. He concludes that this chain of evidence goes far toward proving that this bacillus is the germ of yellow fever.

*The British Medical Journal, August* 29, 1903.

**The Relation of the Thymus Gland to Marasmus.**—John Ruhrâh gives a summary of the findings in eighty-five autopsies on the bodies of infants. The studies cover eighteen cases of marasmus. In these the average weight of the thymus gland was 2.2 grams, the normal weight of the gland at birth being 12 grams. With the exception of the seminal infection, the atrophy of the thymus gland was the only lesion found. Histologically, the fibrous capsule of the gland was thicker than normal, and the trabeculæ were also greatly thickened, the increased interlobular tissue frequently cutting the lobules up into irregular masses. Sometimes there was more fibrous tissue present than lymphoid structure. In most of the cases there was an increase in size and a hyaline degeneration of the Hassall bodies. The author concludes that atrophy of the thymus gland is always found in cases of infantile atrophy, and that the condition of the thymus is an index of the general nutrition of the infant. The state of the nutrition of infants, he says, may be estimated by a microscopical examination of the thymus. In those of normal infants the structure of the thymus is unaltered, and the differentiation between cortex and medulla is plainly visible. In moderate atrophy the cortex and medulla are not easily distinguished, while in severe atrophies the changes mentioned above are plainly seen.

**Congenital Dislocation of the Hip.**—F. F. Burghard discusses the treatment of this condition, formulating his conclusions as follows: (1) All cases should be checked by radiography, and no "cure" should be spoken of that is not a true anatomical cure. (2) All cases of congenital dislocation under fourteen years of age should be submitted to treatment; in the great majority improvement will result, while in some a true anatomical cure is brought about. (3) In all these cases Lorenz's manipulations should be tried in the first instance; even should they fail to effect reduction they facilitate any subsequent procedures. (4) The prospect of a cure by Lorenz's "bloodless method" is in direct proportion to the youth of the child, and after the age of four years there is little hope of a true cure by its means. (5) In any case the chances of a true cure by the "bloodless method" are not very great. (6) An open operation should be done whenever a radiograph shows that the "bloodless method" has failed to reduce the dislocation, except perhaps in the case of a very young child—under three years—in whom the manipulations may be repeated. (7) With the open operation no fear need be entertained of shock, bleeding, or sepsis. (8) Under no circumstances should the joint surfaces be remodelled. (9) An open operation is more calculated to result in a cure, as it enables the surgeon to ascertain beyond a doubt when the head of the bone is really in the acetabulum. (10) The open operation is especially suited for cases over four years of age and for those of bilateral dislocation. (11) After the operation the limb should be put up in the position of maximum stability; in the majority of cases this will be similar to Lorenz's position; the limb should be put up in plaster of Paris immediately and the casing should take in the flexed knee; this is essential in order to assure stability of the head of the bone. (12) All tense structures should be stretched or tenotomized as a preliminary measure a week or so previously to the open operation. The after-treatment is practically identical with that of the Lorenz method.

*Münchener medicinische Wochenschrift, August* 18, 1903.

**Alcoholism and Beer.**—Georg Keferstein deplores the widespread use of beer in Germany, and says that so far as pathological lesions are concerned, no appreciable differences exist between beer drinkers and those who are addicted to the stronger alcoholic liquors. Furthermore the early idea that beer drinking would largely do away with the use of brandy, whiskey, etc., has proved fallacious so far as Germany is concerned. The nutritious qualities of beer which have been loudly exploited by many are not to be considered when compared with the damage wrought by the alcohol which it contains. Taken all in all, the substitution of beer for the stronger alcoholic liquors as a beverage has been a failure, since its devotees neither live longer nor show a better mentality than the consumers of brandy, whiskey, etc.

**Resuscitation of the Heart's Action after Removal from the Body.**—Alois Velich reports some interesting studies. The heart of a young dog was taken from his body and buried in snow for six hours. It was then removed from the snow and through the aortic opening Locke's fluid at 35° was slowly poured in. As soon as a small portion of this fluid had been driven through the blood vessels of the heart their occurred a distinct contraction of the auricles and ventricles. A similar result was obtained with a heart which had been frozen in physiological salt solution for twenty-four hours. These results are similar to those obtained by Kuliabko, but the time of exposure to cold is much longer. They show conclusively that their are no important differences between the hearts of cold and warm-blooded animals in the ability to regain their vitality following exposure to low temperatures. The resuscitation of paralyzed hearts have been attempted in various ways. Spina was successful in a case of a dog ten minutes after the heart had ceased to beat, by injecting into an artery in the direction of the heart 200 c.c. of a warm physiological salt solution. The author has accomplished the same result in a dog by a similar injection of physiological salt solution to which 1 per cent. of glucose was added—thus making it similar to Locke's fluid. It is not improbable that paralyzed human hearts can be resuscitated in a like manner, but as yet no similar experiments have been tried upon man.

**Prophylaxis and Therapy of Puerperal Fever.**—H. Fehling recommends, as a prophylactic measure, the routine use of the rubber glove by the obstetrician. This should be used during labor in all vaginal examinations, and under no circumstances should the naked hand be brought into contact with even the external genitals of the patient. Of course before using the gloves they should be thoroughly sterilized by heat. Experimentation has shown that sterilization of the hands is a practical impossibility while rubber gloves are easily rendered sterile by heat. It is therefore apparent that infection by the obstetrician may be prevented by their use. The author has used them exclusively during the past two years in his hospital service with the following satisfactory results: 1901, 802 labors, five severe cases, 11 per cent. mortality, no case of death from sepsis. 1902, 803 labors, one severe case, 8.47 per cent. mortality, no case of death from sepsis. In the treatment of puerperal sepsis the intravenous injections of silver have given, in the author's hands, as good, if not better, results than any other method of treatment. A 2-per-cent. solution of colloidal silver is employed for this purpose, and of this 10 to 20 c.c. are injected into the median vein. Frequently following this there is a rapid improvement in all symptoms, but in many cases no result is produced. In cases in which a favorable result is produced the injections should be repeated if exacerbations occur. About 50 per cent. of the severe cases treated by this method end in recovery, so that while it cannot be regarded as a specific, it is nevertheless a valuable weapon in the treatment of the disease.

*Berliner klinische Wochenschrift, August* 17, 1903.

**Post-typhoid Strumitis.**—K. A. Krause and Carl Hartog report a case of typhoid fever which was followed by a swelling and suppuration of the thyroid gland. This was subsequently evacuated, and from the pus typhoid bacilli were isolated. The enlargement of the thyroid was first noticed during the lysis of the fever. From this time on it increased in size with considerable rapidity. A peculiarity of this case consists in the fact that although the suppurating process was actively going on in the thyroid, no increased temperature was produced thereby, the characteristic lysis not being interfered with.

**Stomach-tube for Use During Narcosis.**—W. Kausch has devised a stomach-tube for use in operations for occlusion of the intestine. As is well known, such patients, when under the anæsthetic vomit with great frequency, and the aspiration of the vomited material often produces a pneumonia which usually carries off the patient. In those cases in which vomiting does not occur the retention of the contents of the stomach and intestine greatly interferes with necessary manipulations during the operation. The attempt has been made to overcome these difficulties by the introduction of the ordinary stomach tube during the narcosis. This has been found unsatisfactory for two reasons: (1) The stomach tube is frequently vomited entire. (2) Stomach and intestinal contents are often evacuated between the tube and the wall of the œsophagus, and aspiration pneumonia hence frequently occurs. Both of these difficulties are obviated by the use of the tube here recommended. It consists of an ordinary stomach tube, to which is attached a thin, hollow rubber sack of 7 cm. diameter when inflated, at its stomach end just above the tubal openings. This sack is connected by a thin rubber tube which runs along the side of the stomach tube, with another rubber sack of the same size, which hangs out of the mouth of the patient. This in turn connects with a small rubber tube that can be tied off at pleasure. When this apparatus is introduced, both of the rubber sacks are deflated. When the tube is in position they are inflated by blowing into the tube, which leads from the upper sack. The lower sack being inflated in the stomach prevents the vomiting of the tube, since it will not pass the cardiac opening. The upper sack acts as a control to the lower sack, as the size of both is the same. By exerting gentle traction upward, while the tube is in the stomach the lower sack completely blocks the cardiac orifice and prevents the leakage of matter between the tube and the œsophageal wall. In other words, all of the matter is evacuated through the tube as is desired.

*Deutsche medicinische Wochenschrift, August* 13, 1903.

**Herpes Gestationis.**—Fritz Callomon reports a case which is similar to those which have been previously observed, excepting that in the following pregnancy a recurrence of the eruption took place and thus absolutely established the validity of the diagnosis. Since the constitutional symptoms which sometimes accompany this trouble may be severe and sufficiently prolonged to seriously threaten the life of the patient, an accurate and early diagnosis is much to be desired, so that the subsequent pregnancies may be guarded against. To this end the publication of typical cases is greatly to be desired.

**The Vital Action of Irritations.**—A. Schücking has conducted a curious series of experiments in that he has taken the eggs of various parasites, submitted them to certain irritations (electric and chemical), placed them in distilled water and then, after a short interval (five minutes), successfully impregnated them while this was impossible with eggs which were not thus irritated. Two facts are therefore apparent: (1) Protoplasmic irritations are capable of preserving the life of the cell against the deadly influence of osmosis. (2) Leaving out of sight the destroying influence of the water which we can control, the uncontrollable intake and outgive of water, upon which the entire chemistry of the cell depends, is in turn dependent upon irritations which work upon the living protoplasm. The fact that living protoplasm is able to maintain its normal amount of water even for a short time against such enormous differences of tension as exist between the cell fluid and the distilled water proves that the cell is able to regulate the osmotic differences of its normal metabolism independent of its intake and outgive of water.

*French and Italian Journals.*

**Ignipuncture in the Treatment of Cutaneous Angiomata.**—E. Daraiquez says that electrolysis and galvanopuncture, while of benefit in the treatment of angiomata, necessitate too complicated an apparatus to be always practicable. Ignipuncture, however, is easily applied and gives excellent results. Patience is the only requisite, and as fibrous and cicatricial tissue require a certain amount of time for their formation, there is no use in having the treatment too frequently repeated. Once a fortnight is all-sufficient. The ignipuncture must penetrate the whole thickness of the tumor, and the various points applied during the treatment should be about a centimeter apart, or even more in very spreading tumors. The author reports five cases successfully treated in children.—*Gazette Hebdomadaire des Sciences Médicales*, August 9, 1903.

**Some Cases of Beriberi.**—V. Tiberio, having observed a number of cases on the ship *Volturno* in Zanzibar, states that the disease is probably due to a special microorganism, as yet unknown, and can occur independently of alimentation, bodily over-exertion, or excesses of any kind. It may begin insidiously, with symptoms which lead one to suspect its existence but do not definitely establish it. In the early stages the specific gravity of the urine is constantly low, then it rises, and may end by being above normal. No special abnormal products are fouhd in the urine. The anæsthesia occurs in zones, and it is to be supposed that the chief lesion is in the central nervous system, especially the spinal cord. The best treatment consists in removing the patients from the locality where they contracted the disease. Hygienic and pharmaceutical treatment are merely coadjuvant.—*Annale di Medicina Navale*, June, 1903.

**Gastric Cough.**—Louis Revol discusses this form of cough which may occur in health as a result of pressure on the epigastrium, or the ingestion of iced drinks; in certain forms of anæmia, in gastric affections, pulmonary troubles, and especially in case of simultaneous lesions of the stomach and the lungs, a condition found most frequently in pulmonary tuberculosis. The cough is dry, usually paroxysmal, frequently repeated, sometimes accompanied by dyspnœa. Vomiting may be present. It is useless, weakening, and interferes with alimentation. Treatment may be directly addressed to the gastric mucous membrane, by diet and by one or two drops of laudanum before meals, or cocaine, 0.001 (gr. $\frac{1}{60}$) of the hydrochlorate in a teaspoonful of lime water. Painting the pharynx with a strong solution of potassium bromide to narcotize the pneumogastric nerve through its pharyngeal branches may be tried, or bromide of potassium be adminstered to act upon the reflex centers. —*Gazette des Hôpitaux*, August 8, 1903.

**The Results of Nephrectomy for Renal Cancer.**—M. Rochel reports the case of a man operated on two years previously, who is so far apparently in perfect health. He would certainly have died before this had the operation not been performed. The author urges its adoption in cases seen at an early stage; cancer is rarely bilateral, it remains for a long while encysted by the fatty or even the renal capsules, and generalization to other viscera occurs late. The chances of good results from nephrectomy are, therefore, excellent. At an early stage the paraperitoneal rather than the peritoneal route can be followed, with lessened danger, and decortication directly from the renal capsule can be performed, thus avoiding the possibility of wounding the vena cava, the intestines, or the pleura. Unfortunately, it is extremely difficult to diagnose renal cancer at an early stage.—*Lyon Médical*, August 9, 1903.

# Book Reviews.

THE REFRACTION OF THE EYE AND THE ANOMALIES OF THE OCULAR MUSCLES. By KENNETH CAMPBELL, M.D., Edin., F.R.C.S., Eng.; Surgeon to the Western Ophthalmic Hospital; Surgeon-Oculist to His Highness the Maharajah and Gaekwar of Baroda. New York: William Wood & Company, 1903.

THIS work is presented in a small volume of 214 pages, is well printed, and contains illustrations in sufficient number properly to elucidate the text. The subject is presented in a manner that can easily be grasped by the student. Abstruse formulæ are avoided, and an effort has apparently been made to remove all obstacles in the way of an easy acquisition, by the reader, of the principles laid down.

The work is one that presents the subject of refraction and anomalies of the ocular muscles from the English point of view, which differed somewhat from that of the advanced American ophthalmologist. Retinoscopy is well but briefly considered. Under the term asthenopia the muscular anomalies of the eyes are described. With few exceptions, the author adheres to the older nomenclature regarding the conditions of the muscles.

The book is well adapted for the student and should be received with favor by the general practitioner.

THE ERRORS OF ACCOMMODATION AND REFRACTION OF THE EYE AND THEIR TREATMENT. A Handbook for Students. By ERNEST CLARKE, Fellow of the Royal College of Surgeons of England; Doctor of Medicine and Bachelor of Surgery of the University of London; Surgeon to the Central London Ophthalmic Hospital; Ophthalmic Surgeon to the Miller Hospital. New York: William Wood & Company, 1903.

THIS is a small volume of 225 pages. It embodies all of the essentials of refraction as it concerns the human eye. The principals of the optics are discussed in a simple, brief, and accurate manner. Where illustrations are needed to make the subject-matter clear they are supplied. The author displays familiarity with the subject born of careful study and experience, and he has succeeded in presenting it attractively and in a form which renders its acquisition by the student comparatively easy.

Considerable attention is given to the subject of asthenopia, which is discussed in this work under two chapters —first, muscular asthenopia; second, retinal asthenopia. The first really deals with muscular anomalies other than true heterotropia, and would be considered in the chapter on heterophoria by American writers.

A chapter is devoted to the subject of the adjustment of spectacles, and a short chapter is given to vision-tests for the services, Army, Navy, railroad services, etc. Test-type for near and for distance vision and an astigmatic chart are supplied.

On the whole, the work is a very excellent one, admirably suited to the use of the student.

THE PRACTICAL DETAILS OF CATARACT EXTRACTION. By H. HERBERT, F.R.C.S., Eng., Major I.M.S.; Professor of Ophthalmic Medicine and Surgery, Grant Medical College; in charge of the Sir Cowasjee Jehangir Ophthalmic Hospital, Bombay; Fellow of the Bombay University. New York: William Wood & Company, 1903.

THIS volume is one of 109 pages and is of convenient size. The work is based on an experience gained by the extraction of two or three thousand cataracts. The operations were performed at the Ophthalmic Hospital in Bombay, India.

The work is divided into five chapters. The first deals with operable cataract and gives a description of the different varieties, discussing briefly the changes which take place in cataractous lenses. The second chapter is devoted to a description of the combined operation, including the preparation of the patient, the dressing, and the after-treatment. The third chapter takes up the consideration of the different methods of operative procedure, corneal section, preliminary iridectomy, the simple operation, capsulotomy, removal of the cortex, etc. The fourth chapter is devoted to the discussion of the complications arising, infection of the wound, prolapse and incarceration of the iris, hemorrhage, secondary glaucoma, detachment of the choroid, etc. In the fifth chapter certain forms of complicated cataract are considered, extraction in high myopia, extraction of dislocated lenses, etc.

There are illustrations of instruments and of some of the procedures. The subject is treated in a clear and direct manner and presents the views of one of experience. The author has adopted or rejected the views of others according as they have proven beneficial or otherwise in his practice.

The methods advocated can be followed with safety. As the extraction of cataract is an operation done almost wholly by the ophthalmologist, the work is of value principally to the ophthalmologist, by whom it will be read with interest and profit, since it sets forth the conclusions of one whose experience has been rather exceptionally large.

THE PREVENTION OF DISEASE. Translated from the German, with an Introduction by H. Timbrell Bulstrode, M.A., M.D., Cantab. D.P.H. Two volumes of 500 pages each. New York: Funk & Wagnalls Co., 1903.

IT is safe to say that very many of those who take up this book for the first time will be both astonished and delighted at the very broad sense in which the term "preventive medicine" is used. The work is unique in that it is an attempt to view human disease in its entirety from the standpoint of preventive medicine, and its chief object is to show the general practitioner how individual prophylaxis may be developed. Professor Martins gives an idea of what is meant by this last term when he says: "To bring up a weakly child, who may be hereditarily tainted, so that it does not succumb to the threatening danger of tuberculous infection, is individual prophylaxis;" and Dr. Rosen significantly adds, that the physician ought not to wait until the microscopical findings and the physical signs point certainly to pulmonary tuberculosis before he begins to treat the patient hygienically and dietetically.

The volume opens with an interesting article on "The History of the Prevention of Disease," by Dr. S. Goldschmidt of Bad Reichenhall. This is followed by an instructive discussion of "General Prophylaxis" by Professor Martins of Rostock, who points out that a scientific scheme of exact individual prophylaxis may be founded on the determination of the relative functional capacity of the organs of the individual by means of exact physical and chemical examination. Then there follow clear and concise treatises by the several contributors, among whom may be mentioned Dr. Richard Rosen, who discusses the diseases of the blood and of metabolism, infectious diseases and diseases of the lungs; Professor Martin Mendelsohn of Berlin, writing upon diseases of the heart; Professor A. Hoffa of Wurzburg, on surgery; Dr. O. Schaeffer of Heidelberg, on nervous diseases; Drs. von Notthafft and Kollmann, on diseases of the urinary organs, and Dr. Max Joseph, on venereal and skin diseases. There are also articles on the eye, the ear, the teeth and mouth, the nose and throat, the digestive organs, mental disease, and the diseases of children.

The translators deserve the highest praise for having succeeded completely in excluding the long and intricate German sentences, so wearisome to the English reader, and in presenting the thoughts of the many contributors in clear, crisp Anglo-Saxon. Those who have been accustomed to view preventive medicine in the narrow sense in which that term is commonly used in this country will find this work indeed a revelation; is is a book to "read, mark, learn, and inwardly digest" in the quiet of one's study. To the thoughtful reader it is an arraignment, by inference at least, of the present-day craze of the public for specialties in medicine, and an earnest plea for the uplifting of the family physician and his restoration to the time-honored place of valued friend and confidential adviser.

THE MEDICAL EPITOME SERIES. Obstetrics. A Manual for Students and Practitioners. By W. P. MANTON, M.D., Adjunct Professor of Obstetrics and Professor of Clinical Gynecology, Detroit College of Medicine; Visiting Obstetrician, Woman's Hospital and Infant's Home; Gynecologist to Harper Hospital, and to the Eastern and the Northern Michigan Asylums for the Insane; Consulting Gynecologist to St. Joseph's Retreat. Series Edited by V. C. PEDERSEN, A.M., M.D., Clinical Assistant at the New York Polyclinic Medical School and Hospital. Illustrated with eighty-two engravings. Philadelphia and New York: Lea Brothers & Co., 1903.

THIS manual of obstetrics will prove of value to both the student and practitioner. It is brief, clear, and comprehensive. The text is unbroken, but at the end of the several chapters a list of questions is placed, so that the volume is suitable for quizzing. The text is presented in twenty chapters, which include all of the essentials of obstetrics. The new born child and its management are considered in closing, and directions are given for feeding a healthy child during the first year, including various formulas for the home modification of milk. The book is completed by a very good index.

ATLAS MANUEL DE GYMNASTIQUE ORTHOPÉDIQUE. Par MADAME NAGEOTTE WILBOUCHEVITCH. Paris: C. Nau, 1903.

THE author states that the book has been written especially for family physicians and others who may have the supervision of children, and thus the opportunity to detect postural deformities of the spine when cure is

still possible. Intractable cases of this class are usually allowed to develop because of carelessness or ignorance, not infrequently on the part of physicians, who assure anxious parents that such deformities are of no importance, or that they will disappear with the growth of the child.

The author aims to show the predisposing causes of postural distortions by a series of photographs. These illustrate:

(1) The effect of habitual posture in infancy, as when a weak or rachitic child is supported on the mother's arm or seated in her lap. (2) Posture during sleep, which may exaggerate pre-existing distortions. (3) Attitudes induced by occupation, illustrating the effect of improper seats for school children, and the like. (4) Attitudes induced by carrying of burdens. Finally some of the pathological causes of deformity.

It is apparent, of course, that these photographs which illustrate the effect of posture in inducing deformity, indicate also the importance of posture as a means of treatment. The various gymnastic exercises are described, together with an account of forcible correction, and of fixation apparatus.

The book is interesting and instructive, and the author is to be congratulated on having so well carried out the purpose indicated in the preface.

PRACTICAL POINTS IN NURSING for Nurses in Private Practice. With an Appendix Containing Rules for Feeding the Sick; Receipes for Invalid Foods and Beverages; Weights and Measures; Dose List; and a Full Glossary of Medical Terms and Nursing Treatment. By EMILY A. M. STONEY, Graduate of the Training School for Nurses, Lawrence, Mass. Late Superintendent of Training School for Nurses, Carney Hospital, South Boston, Mass. Third edition, thoroughly revised. Illustrated with 79 engravings in the text and 8 colored and half-tone plates. Philadelphia, New York and London: W. B. Saunders & Co., 1903.

THE publishers have procured the services of a physician in the revision of this popular work, owing to he untimely death of the author. The book has not lost any of its original usefulness and still shows the same practical character that made it so readily acceptable in its original form. The third edition has been brought thoroughly up to date and can be recommended as a useful nursing guide to those who are doing private work. It teaches the nurse to be equal to emergencies, showing her how to manufacture many things ordinarily procured in the shops.

BACTERIOLOGY. A Manual for Students and Practitioners. By FRED C. ZAPFE, M.D., Professor of Pathology and Bacteriology in the Illinois Medical College. LEA'S SERIES OF POCKET TEXTBOOKS. Edited by BERN B. GALLAUDET, M.D. Illustrated with one hundred and forty-six engravings and seven colored plates. Philadelphia and New York: Lea Brothers & Co., 1903.

THIS manual summarizes, in concise and practical form, the present status of bacteriological knowledge, and is a convenient epitome of the subject for all who are not specialists. The scope of the work is not extensive enough to make possible very detailed expositions of the purely technical and theoretical aspects of the study, but the author has formulated modern views and conclusions in compact form, and the little volume is thoroughly up to date and reliable. The morphology and biology of all the important clinical organisms are described, and satisfactory illustrations of colonies and individuals appended, together with working directions for carrying out the necessary differential stains. There is but little to criticise and much to commend in the book which is well adopted to the requirements of students and practitioners.

HOW TO KEEP WELL. By Floyd M. Crandall, M.D. New York: Doubleday, Page & Co., 1903.

SELDOM does one find in a popular treatise on health so much valuable information and such breadth of view as in this very readable book of unpretentious title. It only claims to be an explanation of modern methods of preventing disease, but it is, in reality, an epitome of common sense and rare good judgment. The work is singularly free from fads and hobbies, and shows its author to be earnest, thoughtful and conscientious, and a passed master in the art of applying the well-known principles and facts of medicine to the every-day needs of life in such a way as to be readily grasped by the popular mind. He has been prompted to undertake this task by the conviction that "the time has come when the medical man should speak, not in his own defence, but in defence of the people, who are easily misled to their own hurt."

The attention of the reader is directed at the outset to the fact that the modern successful physician is the product of a long and elaborate course of preparation, and that poorly equipped quacks and pretenders cannot permanently succeed at the present day. The necessity for specialism is, of course, conceded, but the layman is cautioned against jumping to the dangerous conclusion that all diseases should be treated by specialists, and is reminded that the family physician's greater sense of personal responsibility is an excellent guarantee of the patient's safety; and that when he is not allowed to select the consultant the sick one often falls into the hands of incompetent and unscrupulous persons. The objection to this procedure, that will rise to many lips, is anticipated by the advice, that if the patient fears to trust the attending physician to make such a choice, he should discharge his physician and get one he can trust. It would be well for all concerned if the laity would read and reread the description of what the family physician should be—a description which is admirably summed up in these words: "Let your physician be a man of character—intelligent, educated, tactful, clean—a gentleman who stands well with his professional brethren and has an honorable record."

Space forbids a detailed consideration of the many excellent features of this book. Even physicians of learning and experience may read with interest and profit the chapters on the effects of modern life, the rearing of children, the dangers of middle life and the prevention of breakdown.

MODERN MATERIA MEDICA AND THERAPEUTICS. By A. A. STEVENS, A.M., M.D., Lecturer on Physical Diagnosis in the University of Pennsylvania; Physician to the Episcopal Hospital and to St. Agnes's Hospital; Fellow of the College of Physicians of Philadelphia, etc. Third Edition, entirely rewritten. Philadelphia, NewYork, London: W. B. Saunders & Co., 1903.

THE main difference between this edition and the preceding ones lies in the abandoning of the alphabetical order and substituting for it a pharmacological classification. This is a distinct improvement in the work, from a student's standpoint, and is practically a necessity for a beginner who has no idea of the grouping of drugs. The articles are brought fully up to date, and the author has included in the text all the latest remedies which have shown themselves to be useful or probably so. The bulk of the work is given to the consideration of drugs, but a fair portion treats of electricity, massage, movement therapy for locomotor ataxia, the Nauheim baths and movements, cold, heat, hypodermoclysis and enteroclysis, lavage, phototherapy and $x$-ray therapy, bleeding, and lumbar puncture. The last portion deals with applied therapeutics in a way far more satisfactory than is usual with most works.

DAS GEWEBE UND DIE URSACHE DER KREBSGESCHWÜLSTE. Unter Berücksichtigung des Baues der einzelligen thierischen Organismen. Von Dr. LUDWIG FEINBERG, arzt. Mit 4 Tafeln. Berlin: August Hirschwald, 1903.

THE author of the present monograph, which is one of the most convincing that has yet appeared, is a staunch supporter of the parasitic theory of the causation of malignant tumors. He ascribes the confusion that has arisen in the study of the subject and the discordance in the conclusions of the various investigators to a lack of sufficiently extensive zoological training and a deficient knowledge of the morphology and life history of the lower forms of animal life. With characteristic teutonic thoroughness he begins with alpha and pursues the rhizopods, flagellates, sporozoa, and ciliata through every subdivision to the very omega of classification before he allows the point of his labors to germinate in the so-called "histosporidium carcinomatosum." This candidate for the unsavory honors its titles indicates has been demonstrated with great regularity by the author in the carcinomata examined, and he gives detailed descriptions as to the necessary technique. The work is interesting and suggestive and should be read by those concerned with the question it treats.

PRÉCIS D'EXPLORATION EXTERNE DU TUBE DIGESTIF. Par A. CHAILLOU et LÉON MAC-AULIFFE. Paris: A. Maloine, 1903.

IN the preface, Sigaud speaks of the insufficiency of our present methods of clinical examination. This is especially true with regard to the abdominal region—that is, the digestive apparatus and the associated glands. His new method is essentially clinical. It has to do with the vital reaction of the digestive apparatus, its physical condition in the presence of its natural physiological excitant, food. By varying the physical or chemical qualities of food, different reactions of the digestive apparatus are called forth, so that this method is not only clinical and experimental, but it is also therapeutic. The external examination of the digestive apparatus is described in detail, in which the three classical methods are made use of—inspection, palpation, and percussion.

# Society Reports.

## CANADIAN MEDICAL ASSOCIATION.

*Thirty-sixth Annual Meeting, Held in London, Ont., August 25, 26, 27, and 28, 1903.*

**Special Report to the Medical Record.**

(Continued from page 392.)

At St. Joseph's Hospital, Dr. Wishart of London performed Halsted's operation for removal of the mammary gland in the presence of a large number of spectators.

At Victoria Hospital, Dr. Ferguson of Chicago performed a thyroidectomy and Ferguson's operation for hernia.

Dr. McGraw of Detroit did the preliminary steps of gastroenterostomy with the elastic ligature in two cases, but both patients were too far advanced in disease to warrant completing the operation.

A character-sketch under the title of "The Country Doctor" was read by Dr. Sprague of Stirling, illustrating the independence of judgment, and originality of resource developed in the course of rural practice.

Dr. Geo. F. Butler, Alma, Mich., read a paper on "The Inter-relations of Diabetes and Other Constitutional Diseases." The paper was highly commended by Sir James Grant of Ottawa, Dr. Reeves of Toronto, and Dr. Sampson of Windsor.

Dr. George Armstrong of Montreal presented a paper on the subject of "Idiopathic Peritonitis."

**The Treatment of Inebriates.**—Dr. Rosebburgh of Toronto, in a paper on this subject, asked the endorsement by the association for the bill now being urged upon the Ontario Government, proposing the adoption of the Massachusetts' probation system combined with medical treatment.

**Practical Considerations on Intestinal Anastomosis.**—Dr. McGraw read this paper. The question of anastomosis came in for consideration, he said, when the gut had become gangrenous. In his procedure he drew the gangrenous coil out of the abdomen far enough to permit him to unite the two limbs of the bowel at a point where they seemed healthy, by means of a rubber ligature. All of that part which was liable to slough was then fastened outside of the abdomen and the wound closed around it. The immediate result was a false anus, and in two or three days a new channel was cut by the rubber ligature and the false anus became unnecessary. It might then in time close spontaneously or be closed by the simple operation of inverting and suturing the ends. Stenosis from chronic obstruction were most commonly caused by tumors or cicatricial contractions. These obstructions furnished the largest quota of cases which required the formation of intestinal anastomosis. The differential symptoms incidental to pyloric obstruction were given, and the certainty of a positive diagnosis insisted on. The speaker maintained that a large percentage of pyloric stenoses were benign. A gastroenterostomy by the elastic ligature gave most satisfactory results in those cases. When the pyloric tumor was cancerous it did not forbid, but rather urgently indicated an operation. The relief would prolong life for from one to five years. Stenoses of the duodenum between the orifice of the bile ducts and the stomach, presented about the same symptoms as pyloric obstruction. Beyond this point bile would always be present in the vomit if the bile ducts were open. The distinctive symptoms of the stenoses of the ileum and colon were pointed out. The facts affecting the mortality following operations were discussed. With or without operation the cases became more and more hopeless, as the vomit became green and finally black.

The methods of making an intestinal anastomosis which claimed consideration were three, viz., the suture, the Murphy button, and elastic ligature. The writer's method by elastic ligature was described, and its superiority to the other two methods argued. Its advantages were (1) simplicity and quickness of application; (2) its aseptic quality, for the rubber filled the opening through which it passed so completely that no extravasation was possible; (3) the delay in opening the passage until the intestines have become well glued together; (4) the ability to make with it a communication at any desired part.

**Thrombosis of the Femoral Veins Following Aseptic Laparotomy.**—Dr. E. R. Secord of Brantford reported a case of this nature. The thrombosis occurred two weeks after an aseptic operation for double inguinal hernia, in which the wound healed by first intention. The thrombosis occurred on the left side, where there was much less handling and trauma of the parts, but where a truss has been worn for twelve years. The writer reviewed seventy reported cases of this complication, 73 per cent. of which were shown to be dependent on operations which produced conditions of lessened local tension. He discussed how this factor operated, and indicated the prophylactic and actual treatment. The writer stated in conclusion that no one etiological factor was alone responsible for the occurrence of this complication; the rôle of infection in otherwise non-infective cases did not appear to bear important one; conditions of sudden decrease of pressure dependent on the operation, probably had a causative influence.

**Hour-glass Contraction of the Stomach.**—Dr. Howitt of Guelph reported two cases of this nature with operation. One was complicated by an ulcer on the posterior wall of the stomach, and the other by cancer. The first patient permanently recovered as a result of the operation; the life of the latter was prolonged eleven months.

Dr. Ferguson complimented the writer upon his cases and approved of his method of operation.

**Address in Surgery.**—Dr. H. A. Ferguson of Chicago delivered the address in surgery. His subject was "The Surgery of To-day," in which he reviewed the present day advances and the future-day prospects.

**A Case of Brain Tumor.**—Dr. Wishart of London reported this case. Patient aged sixty-seven, male, under the care of Dr. Johnson of Sarnia. In December, 1901, he had an attack of tremor and spasm, commencing in the thigh of the left side and extending to the leg, which was painful and jerky. The attack lasted about five minutes. In January or February, 1902, he had other similar attacks. An attack in April was more severe and involved the whole left side of the body, and was attended by difficult breathing. Attacks recurred in August, September, and October. After the attack in October, the mind did not regain clearness, the patient was feverish and prostrated and lost flesh. He was seen by Dr. Wishart in consultation on November 3. Speech was then distinct, but memory was impaired; the man was urinating involuntarily, the knee-jerk was present on both sides, the ankle clonus on the left side, Babinsky's sign was not present, the pupils were equal and responded alike to light, the optic discs were normal, the pulse was 89, temperature 99°, specific gravity of the urine 1020.

A diagnosis of tumor of the brain had already been made by the late Dr. Fraser of Sarnia. Concurring in this diagnosis, Dr. Wishart trephined on the right side of the skull over the leg-center. On removing the disc nothing was visible but the dura mater. On incising the dura mater, beneath it was found a tumor one-half inch in diameter, which was removed. It felt hard and bony to the touch and was subsequently reported by Dr. Nee to be a psammoma. The patient recovered and progressed slowly, and by January, 1903, was mentally clear. On February 17 he had a slight spasm of the left leg. He was able to attend to business, but was not physically strong. He was seen again in May last, when it was apparent that he was growing weaker, being reduced in flesh, and in general physical ill-health. He died a few days ago, but the speaker had as yet received no particulars of his death.

**Dislocation of the Elbow-joint.**—Dr. WISHART also exhibited a case of dislocation of the elbow-joint treated by the open method. He saw the patient four months after the occurrence of the accident. There was an unreduced dislocation of both bones backward, and a fracture of the lower end of the humerus. He cut down and treated the case by open incision. The fracture united and the joint was, at the time of the report, almost normal in its action, the only defect being a slight limitation of flexion and extension.

**Conservative Gynecology.**—Dr. LAPTHORN SMITH of of Montreal thought that in many cases what was called conservative gynecology should rather be termed incomplete work; and that in no department of surgery was it more necessary to be thorough than in this. He had seen so many disappointing results in his own and in others hands, from trying to make half an operation do when the condition present called for a whole one, that he felt less inclined to risk the success of the operation and his own reputation by doing anything less than was necessary. In about a dozen cases he had been obliged to open the abdomen a second time to remove the other ovary which had appeared healthy at the first operation, so that after having treated a patient for at least a year by every possible local and general means without relief, if her condition warranted an operation at all, he endeavored to obtain her consent to his doing what he thinks best for the complete success of the operation. If both ovaries were cystic or sclerotic he removed both. In about twenty cases he had left a small piece of the better ovary and one tube in order to keep up menstruation, and these cases, so far, had been satisfactory. Two or three of the women had since become pregnant and several others had menstruated. In one case he adopted the suggestion of Dr. Howitt of Guelph, which was to scarify the thickened cortex of the ovary through to the stroma, when the tension was immediately relieved, and the incisions became open spaces. Although the space was filled up with exudation which eventually became scar tissue, still it never compressed the ovarian nerve tissue so much as the sclerosed capsule of the ovary. He also thought there was a future for Dr. Robert Morris's suggestion to introduce a piece of healthy ovary into a slit in the back of the broad ligament and hold it there with a stitch. Dr. Morris said that every one of the women on whom he had tried this ovarian grafting had menstruated and one had become pregnant. The author was not in favor of ignipuncture on account of the cicatrix which always followed burns, and which was especially dangerous when situated in tissue so rich in nerves. He had saved diseased tubes and repaired torn ones, and even left in place half of a tube after opening it up; but none of the cases turned out satisfactorily, and two of the patients died from infection of the peritoneum. He was in favor of leaving the uterus even when both tubes and ovaries had to be removed, because it helped to keep the arch of the pelvis supported, and besides it was useful for the purpose of suspending the fallen vagina and bladder. As he had observed, when this latter condition followed a number of operations for the removal of large pus tubes, leaving a large space into which the uterus dropped, it was a custom in nearly every case to perform ventrofixation after removing the tubal abscesses. In vaginal hysterectomy he left the ovaries and tubes in all cases except those in which the uterus was the seat of advanced cancer. When a patient had many diseased conditions which could not be cured without an operation, he endeavored in every case to perform all the operations necessary at one sitting. With good nurses and well-trained assistants he had many times done dilatation, curetting, repair of lacerated cervix, anterior and posterior colorrhaphy, removal of both ovaries and tubes, ventrofixation, and removal of the vermiform appendix in an hour and twenty minutes. By tying all arteries before cutting them and the use of hemostats, not more than four ounces of blood need be lost, nor for the anæsthesia need more than four ounces of A. C. E. mixture be used.

At 5 P.M. the association was given a trolley ride to Springbank Park. In the meantime ladies accompanying members of the association were entertained at the Kennels by the ladies of London. Both parties were conveyed by electric cars to the asylum at 7 P.M., where over 300 guests were entertained at a banquet.

*Thursday, August 27—Third Day.*

On Thursday the members of the association to the number of 200 made an excursion to Detroit as the guests of Parke, Davis & Co. The entertainment comprised a cruise on the Detroit River, inspection of laboratories, and a banquet at the Russell House.

*Friday, August 28—Fourth Day.*

**The Election of Officers** resulted as follows: *President*, Dr. S. J. Tunstale of Vancouver, B. C.; *Secretary*, Dr. George Elliott of Toronto; *Treasurer*, Dr. Small of Ottawa.

Three hundred and two members registered at the meeting, the largest attendance, with one exception, in the history of the association.

Vancouver, B. C., was selected as the next place of meeting.

*Seventeenth Annual Meeting, Held at Washington, D. C., May 12, 13, and 14, 1903.*

**Special Report to the Medical Record.**

DR. PAUL THORNDIKE OF BOSTON IN THE CHAIR.

*Wednesday, May 12—First Day.*

**The Permeability of the Urethra for Certain Silver Salts.**—Dr. EDWIN C. BURNETT of Boston read this paper. He said that during the past four months he had undertaken a series of experiments to determine, if possible, the permeability of the urethral mucous membrane for certain silver salts, and, although he had not concluded them, the results thus far had been so uniformly alike that he felt justified in presenting them to the society as a preliminary report. Argyrol was the salt he had experimented with. As this salt was very soluble and readily washed from animal tissues, it was necessary to find some means of precipitating it in an insoluble form in the tissues, and, at the same time, to have the precipitate distinguished from tissue elements by its color; a solution of hydrogen sulphide slightly acidulated with hydrochloric acid was found well adapted for this purpose. This produced an insoluble black stain of dead tissues that had first been immersed in the solution. In the first series of these experiments the urethræ of dogs were injected with solutions of the salt, the strength of which varied from 1 per cent. to 5 per cent. This was repeated for six days, and on the last day, after washing the urethræ thoroughly so that no post-mortem staining could take place, the urethræ were removed. The tissues were then immersed in a solution of hydrogen sulphide to fix the silver taken up by the cell and were then prepared for the microscope. In the next series of cases silver nitrate was used. In the third series rabbits were used instead of dogs. In all the experiments the results were the same. It was found that the silver solutions did not penetrate, only the upper surface of the top layer of cells showing a trace of silver in the form of a thin black line of silver sulphide, the result of the reduction of the residue of the two silver salts by the hydrogen sulphide left after washing.

**Infection of the Prostate.**—Dr. JOHN VAN DER POEL of New York said that the element of infection of the prostate should be more often considered because, in a large number of cases, the posterior urethra becomes infected, and more quickly than is generally supposed. The

## CANADIAN MEDICAL ASSOCIATION.

*Thirty-sixth Annual Meeting, Held in London, Ont., August 25, 26, 27, and 28, 1903.*

**Special Report to the Medical Record.**

(Continued from page 392.)

At St. Joseph's Hospital, Dr. Wishart of London performed Halsted's operation for removal of the mammary gland in the presence of a large number of spectators.

At Victoria Hospital, Dr. Ferguson of Chicago performed a thyroidectomy and Ferguson's operation for hernia.

Dr. McGraw of Detroit did the preliminary steps of gastroenterostomy with the elastic ligature in two cases, but both patients were too far advanced in disease to warrant completing the operation.

A character-sketch under the title of "The Country Doctor" was read by Dr. Sprague of Stirling, illustrating the independence of judgment, and originality of resource developed in the course of rural practice.

Dr. Geo. F. Butler, Alma, Mich., read a paper on "The Inter-relations of Diabetes and Other Constitutional Diseases." The paper was highly commended by Sir James Grant of Ottawa, Dr. Reeves of Toronto, and Dr. Sampson of Windsor.

Dr. George Armstrong of Montreal presented a paper on the subject of "Idiopathic Peritonitis."

**The Treatment of Inebriates.**—Dr. ROSEBURGH of Toronto, in a paper on this subject, asked the endorsement by the association for the bill now being urged upon the Ontario Government, proposing the adoption of the Massachusetts' probation system combined with medical treatment.

**Practical Considerations on Intestinal Anastomosis.**—Dr. MCGRAW read this paper. The question of anastomosis came in for consideration, he said, when the gut had become gangrenous. In his procedure he drew the gangrenous coil out of the abdomen far enough to permit him to unite the two limbs of the bowel at a point where they seemed healthy, by means of a rubber ligature. All of that part which was liable to slough was then fastened outside of the abdomen and the wound closed around it. The immediate result was a false anus, and in two or three days a new channel was cut by the rubber ligature and the false anus became unnecessary. It might then in time close spontaneously or be closed by the simple operation of inverting and suturing the ends. Stenosis from chronic obstruction were most commonly caused by tumors or cicatricial contractions. These obstructions furnished the largest quota of cases which required the formation of intestinal anastomosis. The differential symptoms incidental to pyloric obstruction were given, and the certainty of a positive diagnosis insisted on. The speaker maintained that a large percentage of pyloric stenoses were benign. A gastroenterostomy by the elastic ligature gave most satisfactory results in those cases. When the pyloric tumor was cancerous it did not forbid, but rather urgently indicated an operation. The relief would prolong life for from one to five years. Stenoses of the duodenum between the orifice of the bile ducts and the stomach, presented about the same symptoms as pyloric obstruction. Beyond this point bile would always be present in the vomit if the bile ducts were open. The distinctive symptoms of the stenoses of the ileum and colon were pointed out. The facts affecting the mortality following operations were discussed. With or without operation the cases became more and more hopeless, as the vomit became green and finally black.

The methods of making an intestinal anastomosis which claimed consideration were three, viz., the suture, the Murphy button, and elastic ligature. The writer's method by elastic ligature was described, and its superiority to the other two methods argued. Its advantages were (1) simplicity and quickness of application; (2) its aseptic quality, for the rubber filled the opening through which it passed so completely that no extravasation was possible; (3) the delay in opening the passage until the intestines have become well glued together; (4) the ability to make with it a communication at any desired part.

**Thrombosis of the Femoral Veins Following Aseptic Laparotomy.**—Dr. E. R. SECORD of Brantford reported a case of this nature. The thrombosis occurred two weeks after an aseptic operation for double inguinal hernia, in which the wound healed by first intention. The thrombosis occurred on the left side, where there was much less handling and trauma of the parts, but where a truss has been worn for twelve years. The writer reviewed seventy reported cases of this complication, 73 per cent. of which were shown to be dependent on operations which produced conditions of lessened local tension. He discussed how this factor operated, and indicated the prophylactic and actual treatment. The writer stated in conclusion that no one etiological factor was alone responsible for the occurrence of this complication; the rôle of infection in otherwise non-infective cases did not appear to be an important one; conditions of sudden decrease of pressure dependent on the operation, probably had a causative influence.

**Hour-glass Contraction of the Stomach.**—Dr. HOWITT of Guelph reported two cases of this nature with operation. One was complicated by an ulcer on the posterior wall of the stomach, and the other by cancer. The first patient permanently recovered as a result of the operation; the life of the latter was prolonged eleven months.

Dr. FERGUSON complimented the writer upon his cases and approved of his method of operation.

**Address in Surgery.**—Dr. H. A. FERGUSON of Chicago delivered the address in surgery. His subject was "The Surgery of To-day," in which he reviewed the present day advances and the future-day prospects.

**A Case of Brain Tumor.**—Dr. WISHART of London reported this case. Patient aged sixty-seven, male, under the care of Dr. Johnson of Sarnia. In December, 1901, he had an attack of tremor and spasm, commencing in the thigh of the left side and extending to the leg, which was painful and jerky. The attack lasted about five minutes. In January or February, 1902, he had other similar attacks. An attack in April was more severe and involved the whole left side of the body, and was attended by difficult breathing. Attacks recurred in August, September, and October. After the attack in October, the mind did not regain clearness, the patient was feverish and prostrated and lost flesh. He was seen by Dr. Wishart in consultation on November 3. Speech was then distinct, but memory was impaired; the man was urinating involuntarily, the knee-jerk was present on both sides, the ankle clonus on the left side, Babinsky's sign was not present, the pupils were equal and responded alike to light, the optic discs were normal, the pulse was 89, temperature 99°, specific gravity of the urine 1020.

A diagnosis of tumor of the brain had already been made by the late Dr. Fraser of Sarnia. Concurring in this diagnosis, Dr. Wishart trephined on the right side of the skull over the leg-center. On removing the disc nothing was visible but the dura mater. On incising the dura mater, beneath it was found a tumor one-half inch in diameter, which was removed. It felt hard and bony to the touch and was subsequently reported by Dr. Nen to be a psammoma. The patient recovered and progressed slowly, and by January, 1903, was mentally clear. On February 17 he had a slight spasm of the left leg. He was able to attend to business, but was not physically strong. He was seen again in May last, when it was apparent that he was growing weaker, being reduced in flesh, and in general physical ill-health. He died a few days ago, but the speaker had as yet received no particulars of his death.

**Dislocation of the Elbow-joint.**—Dr. WISHART also exhibited a case of dislocation of the elbow-joint treated by the open method. He saw the patient four months after the occurrence of the accident. There was an unreduced dislocation of both bones backward, and a fracture of the lower end of the humerus. He cut down and treated the case by open incision. The fracture united and the joint was, at the time of the report, almost normal in its action, the only defect being a slight limitation of flexion and extension.

**Conservative Gynecology.**—Dr. LAPTHORN SMITH of of Montreal thought that in many cases what was called conservative gynecology should rather be termed incomplete work; and that in no department of surgery was it more necessary to be thorough than in this. He had seen so many disappointing results in his own and in others hands, from trying to make half an operation do when the condition present called for a whole one, that he felt less inclined to risk the success of the operation and his own reputation by doing anything less than was necessary. In about a dozen cases he had been obliged to open the abdomen a second time to remove the other ovary which had appeared healthy at the first operation, so that after having treated a patient for at least a year by every possible local and general means without relief, if her condition warranted an operation at all, he endeavored to obtain her consent to his doing what he thinks best for the complete success of the operation. If both ovaries were cystic or sclerotic he removed both. In about twenty cases he had left a small piece of the better ovary and one tube in order to keep up menstruation, and these cases, so far, had been satisfactory. Two or three of the women had since become pregnant and several others had menstruated. In one case he adopted the suggestion of Dr. Howitt of Guelph, which was to scarify the thickened cortex of the ovary through to the stroma, when the tension was immediately relieved, and the incisions became open spaces. Although the space was filled up with exudation which eventually became scar tissue, still it never compressed the ovarian nerve tissue so much as the sclerosed capsule of the ovary. He also thought there was a future for Dr. Robert Morris's suggestion to introduce a piece of healthy ovary into a slit in the back of the broad ligament and hold it there with a stitch. Dr. Morris said that every one of the women on whom he had tried this ovarian grafting had menstruated and one had become pregnant. The author was not in favor of ignipuncture on account of the cicatrix which always followed burns, and which was especially dangerous when situated in tissue so rich in nerves. He had saved diseased tubes and repaired torn ones, and even left in place half of a tube after opening it up; but none of the cases turned out satisfactorily, and two of the patients died from infection of the peritoneum. He was in favor of leaving the uterus even when both tubes and ovaries had to be removed, because it helped to keep the arch of the pelvis supported, and besides it was useful for the purpose of suspending the fallen vagina and bladder. As he had observed, when this latter condition followed a number of operations for the removal of large pus tubes, leaving a large space into which the uterus dropped, it was a custom in nearly every case to perform ventrofixation after removing the tubal abscesses. In vaginal hysterectomy he left the ovaries and tubes in all cases except those in which the uterus was the seat of advanced cancer. When a patient had many diseased conditions which could not be cured without an operation, he endeavored in every case to perform all the operations necessary at one sitting. With good nurses and well-trained assistants he had many times done dilatation, curetting, repair of lacerated cervix, anterior and posterior colorrhaphy, removal of both ovaries and tubes, ventrofixation, and removal of the vermiform appendix in an hour and twenty minutes. By tying all arteries before cutting them and the use of hemostats, not more than four ounces of blood need be lost, nor for the anæsthesia need more than four ounces of A. C. E. mixture be used.

At 5 P.M. the association was given a trolley ride to Springbank Park. In the meantime ladies accompanying members of the association were entertained at the Kennels by the ladies of London. Both parties were conveyed by electric cars to the asylum at 7 P.M., where over 300 guests were entertained at a banquet.

*Thursday, August 27—Third Day.*

On Thursday the members of the association to the number of 200 made an excursion to Detroit as the guests of Parke, Davis & Co. The entertainment comprised a cruise on the Detroit River, inspection of laboratories, and a banquet at the Russell House.

*Friday, August 28—Fourth Day.*

**The Election of Officers** resulted as follows: *President*, Dr. S. J. Tunstale of Vancouver, B. C.; *Secretary*, Dr. George Elliott of Toronto; *Treasurer*, Dr. Small of Ottawa.

Three hundred and two members registered at the meeting, the largest attendance, with one exception, in the history of the association.

Vancouver, B. C., was selected as the next place of meeting.

## THE AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

*Seventeenth Annual Meeting, Held at Washington, D. C., May 12, 13, and 14, 1903.*

**Special Report to the Medical Record.**

DR. PAUL THORNDIKE OF BOSTON IN THE CHAIR.

*Wednesday, May 12—First Day.*

**The Permeability of the Urethra for Certain Silver Salts.**—Dr. EDWIN C. BURNETT of Boston read this paper. He said that during the past four months he had undertaken a series of experiments to determine, if possible, the permeability of the urethral mucous membrane for certain silver salts, and, although he had not concluded them, the results thus far had been so uniformly alike that he felt justified in presenting them to the society as a preliminary report. Argyrol was the salt he had experimented with. As this salt was very soluble and readily washed from animal tissues, it was necessary to find some means of precipitating it in an insoluble form in the tissues, and, at the same time, to have the precipitate distinguished from tissue elements by its color; a solution of hydrogen sulphide slightly acidulated with hydrochloric acid was found well adapted for this purpose. This produced an insoluble black stain of dead tissues that had first been immersed in the solution. In the first series of these experiments the urethræ of dogs were injected with solutions of the salt, the strength of which varied from 1 per cent. to 5 per cent. This was repeated for six days, and on the last day, after washing the urethræ thoroughly so that no post-mortem staining could take place, the urethræ were removed. The tissues were then immersed in a solution of hydrogen sulphide to fix the silver taken up by the cell and were then prepared for the microscope. In the next series of cases silver nitrate was used. In the third series rabbits were used instead of dogs. In all the experiments the results were the same. It was found that the silver solutions did not penetrate, only the upper surface of the top layer of cells showing a trace of silver in the form of a thin black line of silver sulphide, the result of the reduction of the residue of the two silver salts by the hydrogen sulphide left after washing.

**Infection of the Prostate.**—Dr. JOHN VAN DER POEL of New York said that the element of infection of the prostate should be more often considered because, in a large number of cases, the posterior urethra becomes infected, and more quickly than is generally supposed. The

statistics regarding this varied from 10 to 90 per cent. Frank of Berlin gave 33 per cent. In 190 cases which Dr. Van der Poel reported a year ago last June he reported evidences of posterior urethritis in 39 per cent. This condition should not be lightly overlooked, and, although in all cases symptoms were not given, such a condition might exist and then extend to the prostate. The prostate itself, he said, became infected in those instances when the posterior urethra was infected in almost 100 per cent. When once the gonococci reached the prostatic gland, he said it was almost impossible to say how soon we were going to get rid of them. Massage would accomplish a great deal, but we were unable to get at the entire gland in this way, although we could empty the lateral lobes to a greater or less extent in those cases in which the prostatitis was simply catarrhal or follicular in form. He believed one should differentiate between the different forms of prostatitis. That the gonococci might enter the parenchyma of the gland in a short time had been proven by many observers, and after having once obtained a foothold it was a very difficult question to say how soon we were going to get rid of them. If they were confined to the ducts of the gland (a simple catarrhal prostatitis) or to the follicles we might be able to get rid of them by massage. He said, therefore, that we should not forget that in about one-third of the cases there will be shown a posterior involvement, and that it might be taken for granted that the gonococci would extend directly into the prostate in many cases; that, when once in the prostate, they often get into the parenchyma of the organ, and this fact explained why a great many cases did not permanently respond to any of the silver salts, and why reinfection, or more properly autoinfection, of the urethra was so frequent.

**A Case of Strangulation of the Testis Due to Torsion of the Cord.**—Dr. Arthur Tracy Cabot of Boston read this paper. He said that such cases were extremely rare, Dr. Scudder being unable to find more than thirty-two cases in literature. The patient was twenty-six years old. One morning, without previous injury or disturbing cause, he was suddenly seized with a severe paroxysmal pain in the center of the lower abdomen, close above the pubes. He was pallid, nauseated, and covered with sweat. In the afternoon he was so much better that he got up from bed. For two days following the pain was more or less severe and there was an increase in the size of the testicle. Antiseptic fomentations not giving relief, operation was decided upon. The tissues were thick and oedematous. A little blood stain fluid escaped from the tunica vaginalis when opened. The testicle was black, mottled with plum color. The cord was slightly twisted, the rotation being from within outward. One complete twist of the cord untwisted it. The mesorchium was not long and the cord was tightly wrapped about it. The testicle was in a gangrenous condition and had to be removed. Convalescence was uninterrupted.

Dr. Ramón Guitéras of New York reported an interesting experience he had while operating upon a case of varicocele. He found a complete twist of the cord and yet the patient had never felt any pain.

Dr. Van der Poel of New York, said that he thought there were a great many instances in which the cord might become untwisted, or be untwisted by the patients themselves, without their being aware of it. In the Medical Record, June 15, 1895, he reported a case occurring in a medical student who had had an undescended testicle at birth though at two years it came down to the lower part of the scrotum. Suddenly, when he was twenty-one years old, he experienced a sharp pain along the cord with more or less abdominal tenderness, which ran down into the testicle. He did not know the nature of his trouble and continued to work until obliged by the pain to remain quiet. After some manipulation of the parts for two or three hours the pain was relieved. He had similar attacks at intervals of from once in six months to twice in twenty-four hours, which seemed to come on without any known reasons both during the day and night, but they were more frequent when he was up and about. Soon the true nature of the attack became evident. He found that he had a true twist or torsion of the cord, and that he could untwist it himself. When he had these attacks he simply untwisted the testicle from within outward and was relieved.

**Report of a Case of Complete Avulsion of the Scrotum, the Skin of the Penis, and the Left Testis.**—Dr. Alfred C. Wood of Philadelphia related the instance of a man, thirty-three years old, who was engaged in making an adjustment of a ball upon a revolving shaft. His clothing caught and he was taken around a few times and dropped upon the floor. He was taken to the hospital, and the doctor saw him within half an hour after the accident. The scrotum was found to be entirely absent, and the skin of the penis was dissected off as clean as could be well up to the mucocutaneous junction. The left testicle was absent and the right testicle was left exposed in the wound. Hemorrhage from the torn cord was readily controlled. It became a problem to know how to cover the testis. Flaps were finally taken from either thigh and utilized. The patient remained in the hospital about one month, when the testis was well covered. The Reverdin method of skin grafting was employed to cover the penis, small fragments of skin being taken from time to time from the thigh, with the result being all that could be expected. His sexual relations appeared to be perfectly normal.

Dr. Ramón Guitéras of New York cited the instance of an Italian who had gangrene of the scrotum. The scrotum had entirely sloughed away, leaving both testes exposed. An artificial scrotum was made by taking flaps, two from above the pubes and two from below on the inner side of the thigh, all four flaps being egg-shaped and brought together somewhat like the cover of a baseball.

**A New Method of Performing Perineal Section, without a Guide.**—Dr. Chas. L. Gibson of New York presented this communication. A description of his method has already appeared in the report of the Section on Genito-urinary Surgery, New York Academy of Medicine.

**The Conservative Treatment of Cases of Tuberculosis of the Genito-urinary Tract.**—Dr. George Chismore of San Francisco read this paper. He said that improved methods of diagnosis and a clearer recognition of clinical symptoms had brought us to the conclusion that tuberculosis of the genito-urinary tract was far more commonly encountered than was formerly believed, and that such cases were always prolonged in duration, rebellious to treatment and very grave in character. He gave the histories of several cases that had been under his observation for some time, intending to show that it was possible for a person afflicted with undoubted tuberculosis of the genito-urinary tract to live for years a useful life, without surgical attempts to remove the infected organs. In three of these cases the exciting causes were traumatic, falls and muscular strains. Heredity was not at all marked.

Dr. Hugh H. Young of Baltimore did not think we should or could expect so much in the way of conservative treatment as Dr. Chismore because of climatic differences.

Dr. Arthur T. Cabot of Boston believed that the hygienic treatment of certain cases was better, especially when the tuberculosis was disseminated through a complicated series of channels or organs. Now and then the disease would locate itself in the epididymis, for instance, and then operation would be called for.

Dr. W. K. Otis of New York said that no cases appeared alike in genito-urinary tuberculosis, and, therefore, we were unable to tell what was going to happen when any one method of treatment was employed. He had never

been able to find any satisfactory agent for local treatment of a tuberculous cystitis. He much favored the let-alone treatment in all cases of genito-urinary tuberculosis. However, when surgical treatment was deemed advisable it should be done most thoroughly.

Dr. JOHN VAN DER POEL of New York reported a case of tuberculosis of the left testicle with secondary involvement of the prostate as he then thought. The testis itself did not seem to be involved, but the epididymis was removed, thinking it alone was infected. Subsequently operation was necessary to remove the testis as well as that of the opposite side. This case he said demonstrated how careful one should be in advising a partial operation.

Dr. PAUL THORNDIKE of Boston said that in cases of more or less advanced tuberculosis when it seemed advisable to make a palliative operation for the patient's comfort, one would necessarily be deterred from so operating because of the possibility of not removing all the diseased tissue.

**A Case of Calculous Anuria Relieved by Operation.**—Dr. ARTHUR TRACY CABOT of Boston read this paper. The patient was a strong, vigorous man of fifty-seven years of age who, for fifteen years, had suffered from severe pain in the right lumbar region, the pain shooting down into the right groin and into the penis. These attacks occurred about once a year and were accompanied by nausea, vomiting, and a bloody urine. Frequently they were followed by the passage of stones from the bladder, some being one-third of an inch in diameter. Two years ago he had an attack occurring upon the left side. During the past year he had had these attacks upon the right side about once a week. For the past three weeks he had persistent, almost constant, pain in the right side, with nausea, and vomiting each day, but no stones were passed. Only two or three ounces of urine was voided in twenty-four hours. Burning pain occurred in the glans penis. There was great tenderness and rigidity in the right lumbar region, and a sense of great and deep resistance over the right kidney. No prostatic enlargement existed. A skiagraph showed no calculi in the bladder or kidney. He saw the patient twenty-four hours after his admission to the hospital, during which time no urine could be withdrawn by the catheter, and it seemed probable that the right kidney was stopped by a calculus, and that the left kidney was practically useless. The severe attacks in the right kidney were supposed to account for its inactivity. The right kidney was cut down upon and was so large that it was with difficulty lifted out of the wound. It was dark purple in color and dotted with little yellow spots, strongly suggesting miliary tubercles. One of these little abscesses contained a few indeterminate crystals. The pelvis of the kidney was opened and explored but nothing was found. The ureter was followed down into the bladder but nothing could be felt. A drainage tube was introduced into the renal pelvis, the capsule was split along its convexity, and the wound was closed so far as drainage would allow. Within the next twenty-four hours the patient passed 900 c.c. of urine; in the next, 1,500 c.c., and as much more was supposed to have escaped into the dressings. On the fourth day the urine suddenly ceased coming through the bladder and a proportionate amount escaped through into the dressings. Some hours later urination by the bladder was resumed and drainage through the tube then diminished. On the eighth day the tube was removed and leakage through the wound quickly stopped. On the fourteenth day the bladder was washed out and two stones of about the size of a grain of wheat were obtained and a larger stone was felt to click against the Bigelow evacuator. This stone measured 1 cm. in diameter. This was crushed and pumped out on the twenty-fourth day. From this time recovery was practically uneventful. After convalescence the bladder was examined by the cystoscope. The right ureter was three times the normal size and the urine could be seen coming from it in jets. The left ureter was filled by a string of thick pus.

Dr. RAMÓN GUITÉRAS of New York reported the case of a Canadian who suffered from hæmaturia. From his past history he thought of stone in the ureter. A local *x*-ray worker denied the existence of stone, but Dr. Leonard of Philadelphia said one was present just where the ureter passed over the pelvic brim. Operation was performed and just at the point named by Dr. Leonard there was a bulging of the ureter of fusiform character. Palpation of it revealed no stone. It was incised but no stone was found, but a large mass of thick yellow pus of the consistence of Camembert cheese was noted. The ureter was stripped down into the pelvis. The patient's hæmaturia ceased. Although no stone was seen, he thought the probabilities were that there had been one which had passed down into the bladder and escaped through a large perineal opening which the patient had.

**Conservative Perineal Prostatectomy; Presentations of New Instruments and Technique.**—Dr. HUGH H. YOUNG of Baltimore read this paper. The principal objection to the perineal route was the necessity of the suprapubic incision to push the prostate down into the perineum where it could be enucleated. After several months of experiment he had constructed an instrument which could be used from below to draw down the prostate. It consisted of two fenestrated blades attached to shafts, one of which revolved around the other. When the two handles near the outer end, which regulated the rotation, were brought together the blades were approximated and in position for insertion into the bladder through the opening in the membranous urethra. Once introduced above the intravesical limits of the prostatic lobes, the blades could be made to separate by rotating the external blades away from each other, when the instrument would be ready for any traction on its shaft that was necessary to drag down the prostate well into the perineal wound. The fact that many of those requiring prostatectomy were vigorous men in the fifties, with sexual powers well preserved, rendered it important that nothing should be done to injure their manly vigor, and care should be taken not to injure or remove the ejaculatory ducts.

He considered the exaggerated dorsal lithotomy position the most satisfactory. The perineum should be elevated until it was almost parallel with the floor. He used the median perineum incision, about 6 cm. in length, the posterior limit being quite near the anus, in thin patients; if the patient was large, with the prostate situated deeply, he generally used the inverted "V"-shaped incision. The apex of this incision was just over the posterior part of the bulb and the two branches were each 5 cm. long, the posterior limit being about midway between the anus and ischial tuberosity. After exposing the superficial muscles by blunt dissection the central tendon was caught by a clamp near the bulb and divided. This at once freed the sphincter and the levator ani from the anterior attachment and exposed the rectum drawn forward by the recto-urethralis muscle. In order to reach the membranous urethra and the apex of the prostate this muscle should be divided. This at once exposed the "*espace decollable rétroprostatique*" so well described by Proust. When this muscle was divided the rectum dropped back and one entered the space surrounding the posterior surface of the prostate. Next the membranous urethra was opened upon a sound and a sound of considerable size passed through the incision into the prostatic urethra and bladder. Then the prostatic retractor, already described, was inserted; so soon as the beak was free in the vesical cavity the thumb-screw which fixed the blades in position was loosened, the blades rotated 180 degrees by means of the external blades, and then was fixed by tightening the thumb-screws. Each blade projected laterally so as to engage the intravesical surface of the lateral lobe. As a result of this, a splendid exposure of the entire posterior surface of the prostate was obtained.

Next an incision was made on either side of the median line for almost the entire length of the posterior surface of the prostate and about 1 cm. deep; the two lines should be convergent. The bridge of tissue which was contained between the two incisions contained the ejaculatory ducts, whose preservation was of the utmost importance.

He believed the separation of the capsule from the lateral lobes was best done with a blunt dissector. Capsules were of varying thickness and contained several layers of cleavage. It was important to start not too deeply, going into the prostatic substance, nor too superficially so as to be outside most of the capsule. After the stripping up process had been started correctly it was easily continued by blunt dissectors until first the lateral and then the anterior surface of the lateral lobes had been freed from the capsule. Internal nucleation required considerable care to prevent tearing into the urethra. When the enucleation of the lateral lobe had progressed fairly well on each side, he found it advantageous to have traction made upon the prostate itself, in order to facilitate the separation of the deeper portion. He devised a pair of fenestrated instruments which could grasp the entire lobe and which presented such broad surfaces that no tearing or cutting of the capsule could result. After shelling out the lateral lobes attention should be directed to the median portionof the prostate. The prostatic retractor could be used now with great advantage. Abundant vesical drainage should be provided for, as a small tube may easily become plugged by blood clots and cause great annoyance. He deemed it advisable to keep up continuous irrigations while the patient was being returned to his room, so as to prevent clogging of the drainage tube with blood clots during transit.

He had now operated upon twelve cases with the prostatic retractor and generally by the technique described. All these patients were living and well. All could empty their bladders completely, and none used the catheter.

*Thursday, May 13—Second Day.*

**Acute Vesiculitis—Especially Treatment.**—Dr. JAMES P. TUTTLE of New York read this paper. The chief object of his paper was a prophylactic one, to call attention to the harm often done to the rectum by unwise efforts to treat vesiculitis through that organ. He said that the onset of acute vesiculitis was usually in the course of an acute posterior urethritis. It might be due to gonorrhœa, colon bacillus, tuberculosis, or simple pus infection. It had been rare, in his experience, in those cases which had not been subjected to instrumentation, or forcible irrigation of the posterior urethra. It seemed possible to him that the hydrostatic pressure exerted by the Valentine method on the deep urethra in cases of spasm of the neck of the bladder might easily distend the ducts and carry the infectious secretions up toward the vesicles. The disease may come from other causes than gonorrhœa. Aside from the painful erections and emissions, frequent and straining efforts at urination and sometimes retention of urine, most of the symptoms were referred to the perineum and rectum. There usually occurred aching in the sacrum and pelvis, rectal tenesmus, pain on defecation shooting down the legs into the testicles and to the end of the penis just as was often found in ulcer of the rectum. Diagnosis could only be made by an examination through the rectum, and this was best made with the patient in the knee-chest position and with the bladder moderately filled with urine. The finger in the rectum could then make out an unusual heat, tenderness, swollen, irregular masses leading upward and outward from the lateral lobes of the prostate. Usually the prostate was swollen and tender.

**Treatment.**—After experimenting very largely, he found that, in all such conditions requiring prolonged irrigations, two soft catheters of rubber were more satisfactory than the metal irrigators. In the very early stages cold water gradually lowering the temperature from 90° to 50° by putting ice in the reservoir after the flow had begun was best. The bag should not be so high as to cause a forcible injection of the fluids. Prolonged rather than intense cold was to be desired. After the acute symptoms had subsided one should change from cold to heat, but one should be careful not to raise the heat too high; 110–115° F. was as hot as the water should ever be. To this he advised the adding ½ to 2 per cent. hydrastis. When the swelling and pain persisted irrigations over the vesicles through the rectal speculum gave great relief, and would often start up resolution when nothing else would. Temperature was best reduced by the application of guaiacol along the course of the vas deferens. Pain was best relieved by aconite or acetanilid, or phenacetin. Opium should be avoided on account of its constipating effects. Frequent rectal examinations should be avoided. Hydrastis and ergot internally had good effects in chronic conditions.

Dr. EUGENE FULLER of New York emphasized the importance of rest, with elevation of the hips, the use of the bed-pan, enemata, etc., in the treatment of acute vesiculitis. If such a treatment be pursued few cases will run on to a chronic condition. When dealing with acute suppurative processes he advised against fretting them too much.

Dr. GEORGE K. SWINBURNE of New York deprecated the use of forcible urethral irrigations. He used urethral irrigations a great deal, and had never had a case of acute urethritis or prostatic abscess, or other bad result from its use, because he never used force and so avoided distending the urethra too much. In acute vesiculitis he had used the Chetwood tube with pleasing results.

**A Further Report on the Author's Method of Exposing and Draining the Seminal Vesicles.**—Dr. EUGENE FULLER of New York read this paper. He reviewed his former paper read before the New York County Medical Association, and published in the *Journal of the American Medical Association*, May 4, 1901, entitled "A New Operative Method to Expose the Seminal Vesicles and Prostate for the Purpose of Extirpation and Drainage, a Preliminary Report." In order to facilitate an accurate dissection through the soft, elastic and yielding perineal and pelvic structures they should be made to assume as stable a position as possible, and that could only be accomplished by making them taut. To accomplish this the patient with his thighs sharply flexed was put belly downward on a Trendelenburg table, the buttocks protruding somewhat over the end, while the flexed thighs straddle the table. The end of the table was then inclined upward quite sharply. The body was maintained in this position by sand-bags, strappings, and the attention of attendants. An antiseptic, lubricated cotton tampon, with a tape attached, was pushed into the previously cleansed rectum, well up into the region of the sigmoid, in order to guard against bowel leakage. No catheter was necessary or advisable, as in the Von Dittel operation, but the bladder was emptied before the administration of the anæsthetic. The external incision consisted of two somewhat converging longitudinal cuts, which were connected at their dependent and proximal extremities by a transverse cut. The longitudinal cut to the operator's right began a little above the patient's coccyx and just inside his right ischium, and extended downward and slightly inward, keeping just within the border of that bone, passing the tuber ischii and ending somewhat below that tuberosity at a point laterally and about three-fourths of an inch anteriorly to the anterior margin of the anus. The longitudinal cut to the operator's left corresponded exactly to the one just described. The transverse cut connected the converging ends, dividing the perineum transversely about three-fourths of an inch anterior to the anterior margin of the anus. He incised deeply along the longitudinal cuts, through the fatty tissue of the ischiorectal

space, and divided above a few of the lower fibers of the glutens maximus muscle. The transverse cut was then deepened, the anterior layer of the deep fascia being cut through. Great care was taken to avoid wounding the sphincter muscle. The forefinger of the operator's left hand was next introduced into the rectum, the ball of the tip turned downward against the anterior rectal wall, while the corresponding thumb pressed against the loosely dissected rectum, the hand at the same time exercised upward traction. With the right hand the operator dissected more deeply, cutting through the levator ani muscle and the visceral layer of the pelvic fascia. The pathway of dissection between the urethra and the rectal wall was very narrow, and the forefinger in the rectum acted as a most important guide. The stroke of the knife was inward and toward the rectal wall. The tip of the finger was moved so that it was just behind the portion of the rectal wall where the dissection was being made. This protected against perforation of the rectal wall and the urethra escaped damage. In case the lower portion of the lateral incisions have not been made deep enough to sever the levator ani muscle, they can now be made so. Next the operator's right forefinger was inserted along the dissection, and kept just below the rectal wall until it passed through the cut in the visceral layer of the pelvic fascia and entered the lymph space which lies between the prostate and the rectal wall. When this space was reached the left forefinger was passed in alongside the right and the path of the wound divulsed by separating the fingers. By this process the loose rectal connections were stripped from the seminal vesicles and posterior bladder wall, leaving those parts exposed to direct surgical attack. The operation having been completed for which the incision was made, the walls of the wound were carefully adjusted by deep sutures, so as to bring the rectum back into its original position. A space for gauze packing was left in the middle portion of the transverse cut. If the sutures around the rectal portion of the wound were not deep, so as to allow the sphincter to become firmly attached to the outlying structures, some tendency to rectal prolapse might eventually develop. Temporary retention of urine was apt to develop, especially when considerable gauze packing was left, connecting the deep track of the wound with the surface. As the tissues in these parts were well nourished first intention was the rule. This operation rendered direct surgical attack feasible in many rebellious forms of seminal vesicular disease, which were formerly left unaided, or which have responded unsatisfactorily to palliative measures. He had opened and drained thickened and catarrhally distended seminal vesicles, freed them from dense inflammatory adhesions, and removed a neoplasm from one of them, and had entirely extirpated one. At the time the first paper was written the author had employed the operation on five occasions. For a period of nine months afterward he did not employ the operation but followed the cases upon which he had operated. The final results being satisfactory he employed it in a second series of twelve cases. In the first series the operation was done in three instances to expose chronically diseased seminal vesicles, for incision and drainage, the sacs were opened longitudinally and the interiors were subjected to gentle curretage, after which gauze packing was temporarily introduced. In one instance a seminal vesicle was opened longitudinally and a fibrous tumor removed. In the second series the operation was performed in nine cases for the relief of chronic seminal vesiculitis, and three times it was employed to drain acute peri-seminal-vesicular abscesses. The oftener he had performed the operation the more satisfactory it had proved. There had been no deaths, no complications and no alarming symptoms. In about two-thirds of the cases post-operative retention persisted for four or five days, requiring the passage of a soft rubber catheter. In the cases of chronic seminal vesiculitis the gauze packing was removed on the third or fourth day. In most instances the external wound was kept open by means of rubber drainage tubes for a week longer. In a considerable number of cases there was prompt relief from reflex symptoms, while in some several months elapsed before such relief was experienced. In most of the cases there was thorough restoration of the sexual function, though it might be four or five months before this result was attained. He advised patients against sexual excitement for several months after convalescence, lest they do damage to the seat of operation. He felt that his experience with this operation when employed to drain seminal vesicles was past the experimental stage, and he strongly advocated it in aggravated instances of seminal vesiculitis associated with marked subjective symptoms, which persisted in spite of his treatment of stripping the organs by means of the finger introduced into the rectum. The stripping method took considerable time, perhaps from six to nine months. He did not recommend the operation in tuberculous seminal vesiculitis. He found this method of reaching and draining deep suppurations either about the seminal vesicles or prostate most satisfactory. If the abscess was back of the prostate his operation avoided injuring that gland or the ejaculatory ducts. He always feared the operation per rectum lest bowel leakage into the tissues might give trouble, or in case of an abscess just on the verge of spontaneously discharging itself into the bladder a vesico-rectal fistula might persist. No surgical objections could be raised against the drainage of suppuration by his method since the dissection employed reached the focus of trouble without injury to any of the adjacent organs. Speedy and safe convalescence ensued, and there was little or no danger of subsequent complications. The only objections to the operation was that it required more skill than a cystotomy, with incision through the trigonum, or an incision through the rectum.

Dr. JAMES P. TUTTLE of New York, in order to prevent any contamination of the operative field by the rectal contents, recommended that a metal ring with a groove running around it, with four holes in it, be employed in this way: An ordinary condon should first be tied around the groove in the metal ring, which is then fastened just inside the anal margin. The condon is then inverted, and this would prevent the fæces coming down as well as protect the surgeon's hand from the fecal contents.

Dr. HUGH H. YOUNG of Baltimore believed that too much attention was paid to the vesicles and not enough to the prostate. He said that a chronic prostatitis was more difficult to cure than a chronic vesiculitis, and that it happened very often a cure of both resulted from attention being paid alone to the chronic prostatitis.

Dr. E. L. KEYES, Jr., of New York, always had fancied that a rectal incision was adequate to take care of that kind of cases; he had never found the dangers of infection increased by an incision through the rectum which was a simpler matter than going through the perineum. He related an instructive instance occurring in a man who was in catheter life. He was called to the country to open an abscess, the incision being made through the rectum. Before operating there was no pus in the urine, but after the operation it became loaded with pus. The parts were irrigated with boric-acid solution for eight or ten weeks and he was reported to be no better. He was still passing urine through his rectum. The irrigation was stopped and, six weeks later, the hole closed and remained closed.

Dr. Fuller said he had never had infection from the rectum from following the method of operating advocated, but thought the suggestion of Dr. Tuttle a good one. He believed that a greater effort should be made to differentiate between diseases of the prostate and those of the vesicles. He thought the time would soon come when more would be done for such sufferers by operative procedures. One of the dangers of opening through the rectum was from the urine, and an

operation which avoided such a possibliity would be better than when we obtained drainage elsewhere.

**A Vesical Calculus of Unusual Dimensions.**—Dr. ABNER POST of Boston presented this unusual specimen. The patient was a man, sixty-six years old. He dated the beginning of his trouble from a urethral hemorrhage which he believed occurred fourteen years ago. Since then he had had almost constant discomfort and frequent micturition. For some time he had been compelled to get up every hour of the night to pass his urine. Sometimes his urine would not come until he had raised his leg. It was evident when the doctor first saw him that he had a stone, the removal of which would relieve him of his symptoms. Suprapubic cystotomy was performed and the immense stone was disclosed. It filled the entire vesical cavity. With much difficulty the stone was removed from its bed. To gain sufficient room it was found necessary to divide the recti muscles and to make a transverse incision on each side. The stone weighed 660 grams. It was 11¾ inches in its longest diameter and 10¾ inches in its shorter. The athologist reported that it consisted chiefly of phosphate of calcium and triple phosphates with some carbonate of lime and organized débris. The largest vesical calculus on record was said to be in the possession of the French lithotomist, Morand. It weighed 6 pounds and 3 ounces. An enormous stone, weighing 51 ounces, was long preserved in the hospital of La Charité, Paris. It was extracted after death from the bladder of a poor curate in 1690. Coulson, "On the Bladder and Prostate," said "The largest calculus preserved in our collections is the one which Mr. Cline attempted to extract from the bladder of Sir William Ogilvie; it weighed 44 ounces, and was 16 inches round one axis by 14 round the other. Numerous cases are recorded in which the stone weighed from 5 to 15 or 20 ounces; but how small a proportion they bear to the mass of cases operated on may be gathered from the fact that, of the 703 calculi in the Norwich collection, weighed by Mr. Crosse, only two exceeded 6 ounces in weight, and they were between 6 and 7 ounces."

Dr. HUGH H. YOUNG of Baltimore said that he learned, from a book he had in his possession, that Sir William Ogilvie for five years had found it necessary to stand on his hands, or back up against a wall, in order to urinate; in this way the urine flowed over the top of the stone. The attempt at perineal lithotomy was made in 1816, before the days of anæsthesia. It was stated that Sir William bore the operation with great fortitude. With supplies from a blacksmith, a chisel and hammer, etc., five ounces of the stone were removed, and then Sir William could stand it no longer. The calculus was now in the Museum of the College of Physicians and Surgeons, and had the marks of the work done upon it during the operation, showing where a hole had been gouged out. Last year Dr. Young had seen two calculi which filled the bladder and prostatic urethra, and were practically as big as the one presented by Dr. Post.

**Some Suggestions in the Management of Prostatics About to Enter Catheter Life.**—Dr. GEORGE K. SWINBURNE of New York read this paper. He believed that many patients with prostatic hypertrophy were introduced to catheter life, and allowed to use the catheter themselves, who for a longer or shorter period, by judicious management, could be saved from the frequent self-catheterization with its attendant dangers. The cases varied markedly in the rapidity with which the amount of residual urine increased, according to the situation of the obstruction; but he said there was one element often overlooked, the superinduced congestion, or, rather, œdema of the surrounding tissue, which increased the obstruction and consequently the amount of residual urine. When this obstruction and consequent congestion had been reduced, then the amount of residual urine fell back to an amount due to the mechanical obstruction itself. Many of these patients could be brought back to the condition they were in before the onset of any acute symptoms and kept there for a varying period of time; they would have nocturnal polyuria and a small amount of residual urine, but the urine will be sweet and clean and the bladder remain uninfected; then by careful dieting, abstemious living, the proper amount of exercise, and the local treatment, etc., would cause a lessening of the physicians' visits until they did not exceed two or three a month.

**Cancer of the Prostate.**—Dr. ROBERT H. GREENE of New York presented this communication and said that he had great difficulty in finding any literature which bore upon this subject. Frequent symptoms were pain referred to the perineum, to the rectum, and to branches of the sciatic nerve; the amount of residual urine had little relation to cancer cases. The average age of all cases was sixty-eight years. The size and feel of the growth as found by rectal touch was of no special diagnostic value. There followed secondary lymphatic infection. Autopsies were made on seventy-one men; in 88 per cent. the glands were found to be involved, and in about 35 per cent. the inguinal glands were infected; in about 3 per cent. the axillary glands were involved.

He reported a case of this nature. The patient was sixty years old and had had gonorrhœa forty years previous. At Christmas time, 1901, he had retention of urine and was relieved by catheter. From then on he complained of pain in the right perineal region. There was but little residual urine. Urinary examination was negative. There was no tenderness over the prostate. The bladder was irrigated with nitrate of silver solution and he was given tonics, and all was done that was possible toward improving his general health. The pain continued. He insisted upon an operation. The diagnosis at that time was an abscess of the right lobe of the prostate, or else a small stone incysted in the prostate. The patient was operated upon last June and the prostate was removed. He claimed that the operation injured his sexual functions. The pathologist reported the right lobe of the prostate to be cancerous. Dr. Guitéras presented some photographs of the case.

(To be continued.)

## New Instruments.

### AN INSTRUMENT FOR THE RAPID ESTIMATION OF THE ACIDITY OF THE GASTRIC CONTENTS.

BY C. SIGMUND RAUE, M.D.,
PHILADELPHIA, PA.

IN the investigation of the diseases of the stomach, the estimation of the amount of free hydrochloric acid, combined hydrochloric acid, and the total acidity is, perhaps, the most essential result to be obtained. The usual method is to titrate the gastric contents with decinormal soda solution from a Mohr's burette—a procedure that is tedious and requires, beside the necessary outfit of beakers, graduates, burette, etc., a certain amount of laboratory technique. The instrument shown in the accompanying illustration combines, so to speak, the entire outfit required for a titration, besides being far simpler and easier to carry out. For the sake of convenience the instrument may be called an acidometer.

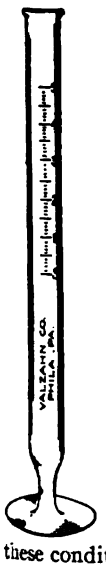
The method of procedure is as follows: Fill the acidometer with filtered gastric contents to the line marked "S" and add a drop of a one-half of one-per-cent solution of dimethylamido-azo-benzol. When free HCl is present, the reagent imparts to the solution a deep red color. This point, however, should be determined beforehand by testing for free HCl with Boas' reagent, or by mixing a drop of the dimethylamido-azo-benzol solution with a drop of the gastric contents on an evaporating dish and noting whether or not the characteristic color change

takes place. Now add, drop by drop, under gentle agitation of the tube, decinormal soda solution until the free acid is neutralized, as indicated by the change of the red color to yellow (pale orange). Read off the amount of decinormal solution that was necessary to get this result, by consulting the scale on the tube (the markings correspond to cubic centimeters and tenths of cubic centimeters) and multiply by twenty. The result indicates the amount of free HCl present. Thus, if five-tenths is the amount of soda solution used, the free acid equals ten (10). By titration, this indicates that in order to neutralize the free acid in 100 c.c of gastric

contents it requires 10 c.c. of soda solution, in this particular instance. The percentage of acid can be calculated by multiplying this result by .00364, but in gastrological work the acidity is recorded, as a rule, in the results obtained by titration, as above

The next step is the estimation of the combined acid. Add a drop of a one-per-cent. solution (alcoholic) of phenolphthalein to the contents of the tube and continue dropping in soda solution until a pink color, not disappearing on agitation, is developed. This indicates the point of neutralization of the combined acid. Note the amount of soda solution required to gain this result and mutliply by twenty. The product represents the amount of combined acid on the same basis as above. Thus, if 2.5 spaces (c.c.) were used the combined acid equals 50.

The sum of free acid (10) and combined acid (50) represents the total acidity. Normally this is from 60 to 65.



Before the above tests are made the actual presence of free HCl should always be determined as described above, and lactic acid should be tested for by Uffelman's reagent—a mixture of a dilute solution of neutral ferric chloride and dilute carbolic acid, forming an amethystine solution changed to canary yellow by lactic acid. When free HCl is present in appreciable amount, lactic acid fermentation is inhibited, and accordingly it may be left out of consideration under normal conditions. In examining the gastric contents of children that have been taking milk, no free HCl will be found, as the acid enters into chemical combination with the milk proteids so completely that it, so to speak, is neutralized. Under these conditions, however, the total acidity is high.

In case only a small amount of gastric contents is obtainable, 2 c.c. may be used in the acidometer, adding water up to the mark "S." The result is then multiplied by fifty instead of twenty. The apparatus is manufactured by the Valzahn Surgical Instrument Company of Philadelphia.

---

**Medical Perils.**—In Beloochistan, when a physician gives a dose, he is expected to partake of a similar one himself as a guarantee of his good faith. Should the patient die under his hands, the relatives, though they rarely exercise it, have the right of putting him to death, unless a special agreement has been made freeing him from all responsibility as to consequences; while, if they should decide upon immolating him, he is fully expected to yield to his fate like a man.—*Tit-Bits.*

## Books Received.

*While the* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

**Insanity and Heredity.**—Dr. Ernest W. White says that heredity plays a large part in the production of insanity. The intermarriage of persons afflicted with grave neuroses, or even with the actual taint of insanity, is too common. Yet it is one which should be prevented, by educating public opinion and morality if possible, or even by State measures.

# Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 5, 1903:

| | Cases. | Deaths. |
|---|---|---|
| Measles | 78 | 5 |
| Diphtheria and croup | 238 | 32 |
| Scarlet fever | 89 | 10 |
| Smallpox | .. | ... |
| Varicella | 15 | ... |
| Tuberculosis | 248 | 127 |
| Typhoid fever | 129 | 23 |
| Cerebrospinal meningitis | ... | .. |

**Bacterioscopical Analysis of Water.**—At the British Congress of the Royal Institute of Public Health, Dr. Savage opened a discussion on the need of a uniform scheme of examination to be adopted in the bacterioscopical analysis of water. The speaker considered the subject under these headings: (1) The collection and transmission of the samples; (2) the data to be ascertained; (3) the processes and procedures of the examination; and (4) the interpretation of the results with regard to the first he detailed the precautions usually adopted, but stated that he was by no means sure that ice-packing preserved the bacterial contents unaltered. As regards the second point he suggested (*a*) number of aerobic organisms per cubic centimeter developing at 37° C.; (*b*) investigation as to the presence of certain organisms especially liable to be associated with sewage or fecal contamination, such as bacillus *coli communis*, bacsillu enteriditis sporogenes, streptococci and proteus organisms; (*c*) examination for bacillus, typhosus, and spirillum choleræ. As regards the third point, he thought that some uniformity might be reached concerning the temperature of incubation, date of counting the colonies, and reaction of the culture medium, but he did not consider they were yet in a position to suggest a standard method for the qualitative examination for bacillus coli, and for bacillus enteriditis sporogenes, it had yet to be determined whether cultural characters alone were sufficient, or whether the inoculation test in addition was necessary. In the discussion that followed, Professor R. T. Hewlett pointed out that chemists had arrived at a more or less uniform procedure, and half a dozen chemists examining the same water would probably all adopt the same method and would obtain the same figures. He thought that some scheme might be formulated to obtain uniformity among bacteriologists, and advocated the formation of a commission to consider the question.—*Lancet*, August 1.

**Use of Radium in Surgery.**—The *Lancet* of July 25 contains a letter from its Vienna correspondent, in which is given a brief account of the recent meetings of the Vienna Gesellschaft der Aerzte, and the discussion thereat on the physiological action of radium. Dr. G. Holzknecht and Dr. G. Schwartz said they had found that the majority of animal tissues, especially the vitreous body and the crystalline lens, became fluorescent under the action of radium, and they concluded that Dr. Loudan of St. Petersburg erred in supposing that there was an irritation of the retina by the radium rays. Dr. A. Exner and Dr. Holzknecht succeeded in obtaining very remarkable therapeutical effects by use of radium. Dr. Exner showed two cases of melanosarcoma of the skin which had been greatly benefited by one exposure of from five to twenty-five minutes to the rays emitted by three milligrams of radium bromide. In a third case, an epithelioma of the lip, which had been operated on twice, but which at the time of the use of radium was as large as a cherry, was exposed to the radium ray six times for from fifteen to twenty minutes. Seventeen days after the first exposure the tumor had decreased in size very remarkably, and its presence could not be recognized by clinical examination three weeks after the first exposure. The general effect of the demonstration was to prove that radium acts as a very important remedy in many malignant diseases, in the treatment of which it will, no doubt, to a great extent, supersede ordinary surgical measures and the application of the Röntgen rays.

**Prevention of Malaria on Shipboard.**—Mr. Evans of the Elder Dempster Line, speaking at the recent British Public Health Congress, said that as long as the taking of quinine was a voluntary matter, so long would malaria remain on shipboard. It would be wise, he thought, to have a board of trade regulation to insist upon a regular "quinine parade." Officers and men should be educated as to the value of quinine and as to the mosquito theory. It would be difficult to exclude mosquitoes altogether from ships, hence the value of quinine. Dr. C. Christy of Liverpool said that Europeans should be segregated and natives excluded. The last he described as being the only measure which afforded the traveler any real hope of safety.

**Health Report.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended August 29, 1903:

### DIFFERENTIAL LEUCOCYTE COUNT IN THE EARLY DAYS OF TYPHOID FEVER.*

A STUDY FROM THE DEPARTMENT OF PATHOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, NEW YORK.

BY HENRY A. HIGLEY, M.D.,
BROOKLYN, N. Y.

THE present knowledge regarding the differential leucocyte count in typhoid fever has been chiefly obtained through the studies of Türck, Naegeli, Ouskow, Thayer, and Winter. From their observations it may be considered as definitely settled that in uncomplicated cases of this disease, the polymorphonuclear neutrophilic leucocytes are relatively and absolutely decreased, while the large mononuclears are always relatively and usually also absolutely increased in number. Furthermore the small mononuclears are relatively and absolutely decreased, normal or increased, the eosinophiles being both relatively and absolutely subnormal. The limits within which these variations usually occur are, however, not accurately settled, since the figures given by different authors vary widely; for example, the average relative reduction of polymorphonuclear neutrophilics as observed in ten cases by Winter is nearly 10 per cent. greater than that found by Thayer in a like number of cases—the observations of both authors having been made with substantially the same technique and at the same period of the disease, namely, during the second week. It is generally supposed and stated, moreover, that these peculiar relative variations in the number of leucocytes in typhoid fever are first manifest during the second week, from which time on they increase in intensity in greater or less degree. This supposition is mainly, if not entirely, based upon the observations of Thayer, since of the observers above-mentioned he is the only one who reports examinations previous to this time—that is, during the first week of the disease. He reports as thus examined, in the first week, twelve cases, and gives the following average figures for the percentages of the various leucocytes present: small mononuclears, 12.9 per cent.; large mononuclears, 12.4 per cent.; polymorphonuclear neutrophilics, 74 per cent.; eosinophiles, .5 per cent.

Curiously enough, in these cases Thayer has not stated the grounds upon which the diagnosis of typhoid fever was made, nor the facts which led him to suppose that the counts were, in truth, made during the first week of the disease. Furthermore, the counts were not made individually by him, but by different internes at the Johns Hopkins Hospital. The number of leucocytes counted in each case varied. In some 200 was the number, while in others upward of 300 were enumerated. I do not bring forward these facts with respect to Dr. Thayer's counts with any intent or desire of minimizing their value, which is great, or of drawing them under any suspicion whatsoever; but simply to make a fair statement concerning the conditions under which they were obtained, and to show that increased observations might demonstrate his conclusions were not universally applicable and to be applied to all cases of typhoid fever during the first week.

In view of all these circumstances, therefore, nearly two years ago I began a series of observations upon the differential leucocyte count in the early days of the disease, utilizing therefor cases as they from time to time appeared in my own practice or in those of other physicians, and which I had the opportunity of examining. I should not deem it worth while at the present time to communicate my results, but for the fact that they vary quite markedly from those found by Thayer during the first week, and having convinced me that in many instances the differential leucocyte count which may be called characteristic of typhoid fever is present, contrary to general supposition, during the first week of the disease.

*Technique.*—The blood drop was obtained in the ordinary manner without pressure.

The smears were made by the cover-glass method and thinly spread. No thick smears in which the leucocytes were entangled in masses of red blood cells were used.

In staining the smears one cover-glass from each patient was stained with Ehrlich's triacid mixture, and the other with either Jenner's or Wright's stain. The manipulations in using these stains were as follows:

Ehrlich's: The smears were fixed by exposing them to dry heat for two minutes at 100°–120° C. They were then covered with the stain and exposed thereto for five minutes. They were then washed off in distilled water, dried between filter paper, and mounted in balsam.

Jenner's: The smears were covered with the stain and exposed thereto for two minutes. During this time they were protected from the air by being placed in small double dishes. They were then washed *actively* in distilled water, dried in the open air, and mounted in balsam.

Wright's: The smears were covered with the stain and exposed thereto in the open air for one minute. Ordinary tap water was then added drop by drop to the stain upon the smear until there appeared upon the surface of the same a yellowish scum. The exposure was then continued for three minutes. They were then washed *actively* in tap water, dried between filter paper, and mounted in balsam.

In making the counts, a $\frac{1}{12}$ oil-immersion objective and a mechanical stage were used. One thousand leucocytes were counted with each stain—that is, in all, two thousand leucocytes from each patient. The count upon each cover-glass was made without interruption until the full number of 1,000 was counted. If interruption unavoidably occurred, the count was begun over again.

*Differentiation of Leucocytes.*—It is not necessary

*Read before the New York Pathological Society.

in this place to consider the differentiation of the leucocytes with the stains which were employed in this work, so far as the polymorphonuclear neutrophilics and eosinophiles are concerned, since no difficulty attaches to the same with any one who has had any experience in the examination of stained blood smears. It is a fact, however, that there is not by different observers a precise uniformity concerning the differentiation of the small from the large mononuclears. For this reason I give the differentiation which has been observed in these studies between these two classes of leucocytes.

Ehrlich's: Those mononuclear non-granular leucocytes which appeared in their entirety of a light blue or green color and were the same size or smaller than a red blood cell, were counted as small mononuclears, and, in addition, all those mononuclear non-granular leucocytes which showed a nucleus of a light blue or green color surrounded by a narrow zone of buff-colored protoplasm, and which in their entirety were not larger than a red blood cell. All mononuclear non-granular leucocytes which were larger than a red blood cell were classified as large mononuclears. In most of these the nucleus was round and symmetrical in form, but in a few it was invaginated. The staining properties of the protoplasm of the large mononuclears varied. In the vast majority it appeared of a buff color, but in a *few* the protoplasm was poorly stained and was somewhat indistinct.

Jenner's: Those mononuclear non-granular leucocytes which stained blue and were the size of a red blood cell or smaller were regarded as small mononuclear leucocytes. All other mononuclear non-granular leucocytes were counted as large mononuclears. Some of these showed a light blue nucleus surrounded by a narow and more or less uneven rim of dark-blue protoplasm.

Wright's: Those mononuclear non-granular leucocytes whose nucleus was of a dark purplish blue color and whose protoplasm was a robin's egg blue, were counted as small mononuclears, provided they were not distinctly larger than a red blood cell. If the latter was the case, they were classified as large mononuclears. In addition, those regarded as large mononuclears were non-granular and mononuclear, their nucleus being a blue or lilac and their protoplasm pale blue or dark. As a rule these latter leucocytes were larger than a red blood cell, but in a few instances they were smaller; in such instances they were classified as small mononuclears.

*Epitome of Cases.*—The number of typhoid cases studied was sixteen. The diagnosis was established subsequent to the count as follows: In seven by the isolation of typhoid bacilli from the fæces, using the Hiss method; in six by the presence of a positive Widal reaction (1-20 or above); and in three, on a clinical basis, by the appearance of a typical typhoid roseola, an enlarged spleen, and a typical clinical course. In these three cases circumstances interfered with the carrying out of either a Widal or isolation test.

In studies of this nature, after having established the diagnosis of the cases examined beyond the peradventure of a doubt, it becomes necessary to demonstrate with as much certainty as possible the fact that the examinations made were in reality conducted at the specified period of the disease to which claim is made. In a disease like typhoid fever such a demonstration becomes at once a matter of the greatest difficulty. When all the circumstances in connection with a given case are taken into consideration, one may honestly feel that he is dealing with a specified period of the disease (suc as in these cases the first week), and yet to prov that such is the case often becomes well-nigh a impossibility. To my mind there is but one facto which can settle such a question beyond a reason able doubt. I refer to the date of the first appear ance of the eruption. Authorities differ concern ing the limiting days of the disease within which th roseola may first appear. Comparatively few giv definite figures. Most say that it usually firs appears during the latter part of the first or th beginning of the second week, and that it may pre cede or succeed this period by a few days. Osler however, does give definite figures, and says from the seventh to the tenth day. While there can be no doubt but that it *may* first appear a few days earlier or later than this period, I nevertheless believe that these dates may be regarded as practical working figures. In the endeavor to establish the date of my examinations, I feel justified in accepting them, recognizing that they are not infallible, but believing that they constitute a standard from which conclusions may safely be drawn. Admitting that in a given series of cases the roseola first appeared on the latter of these days (the tenth), if it can be shown that in each case a given examination was made at least three days previous to this it would appear beyond a reasonable doubt that such an examination was made within the first week of the disease. Of course this presupposes that each case was seen early, and that frequent and careful examinations were made to detect the first appearance of the roseola. In all of these cases such frequent and careful examinations were made, and they were certainly all seen early in the course of the disease. Nine of the sixteen cases respond to this test—that is, the differential and total counts were made at least three days previous to the first appearance of the roseola. Here follows a detailed consideration of each of these nine cases:

CASE I.—L. H., aged twenty-five years. Fairly characteristic prodromal history of typhoid fever. Leucocyte counts made on what was probably the third day. Evening temperature 102.2° F. Pulse 92. Characteristic typhoid roseola first appeared five days thereafter on what was probably the eighth day. Widal reaction (1-20) first positive on what was probably the ninth day. Previous Widal tests had been made on the third and sixth days. No attempts were made to isolate typhoid bacilli from the fæces or urine.

Leucocyte counts made on day above indicated: Total count, 5,250. Differential count:

| | JENNER'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 22.1 per cent. | 19.3 per cent. |
| Large mononuclears.... | 12.4 " | 15.7 " |
| Polymorphonuclear neutrophilics..... | 62.3 " | 62.0 " |
| Eosinophiles..... | 3.1 " | 3.0 " |
| Basophilics (mast-cells) | .1 " | .... |
| | 100. per cent. | 100.0 per cent. |

CASE II.—C. B., aged fifteen years. Fairly characteristic prodromal history of typhoid fever. Leucocyte counts made on what was probably the third day. Evening temperature, 101.8° F. Pulse, 95. Characteristic typhoid roseola first appeared four days thereafter, on what was probably the seventh day. No Widal tests were made. No attempts were made to isolate typhoid bacilli from fæces or urine. Spleen first detected to be enlarged in the latter part of the second week. Subsequent clinical course typical of typhoid fever.

Leucocyte counts made on day above indicated: Total count, 7,200. Differential count:

| | JENNER'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 21.2 per cent. | 22.8 per cent. |
| Large mononuclears.... | 19.4 " | 18.2 " |
| Polymorphonuclear neutrophilics..... | 58.2 " | 57.4 " |
| Eosinophiles..... | 1.0 " | 1.6 " |
| Basophilics (mast-cells) . | .2 " | .... |
| | 100.0 per cent. | 100.0 per cent. |

CASE III.—A. C., aged twenty-nine years. Indefinite prodromal history of typhoid fever. Leucocyte counts made on what was probably the fourth day. Evening temperature, 103° F. Pulse, 98. Characteristic typhoid roseola first appeared five days thereafter, on what was probably the ninth day. Widal reaction (1-40) first positive on what was probably the fourteenth day. Previous Widal tests had been made on the fourth and eighth days. No attempts were made to isolate typhoid bacilli from fæces or urine.

Leucocyte counts made on day above indicated: Total count, 5,200. Differential count:

| | JENNER'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 19.7 per cent. | 20.4 per cent. |
| Large mononuclears.... | 14.0 " | 12.1 " |
| Polymorphonuclear neutrophilics..... | 65.2 " | 65.5 " |
| Eosinophiles..... | 1.0 " | 2.0 " |
| Basophilics (mast-cells). | .1 " | .... |
| | 100.0 per cent. | 100.0 per cent |

CASE IV.—B. N., aged twenty-one years. Characteristic prodromal history of typhoid fever with epistaxis. Leucocyte counts made on what was probably the fourth day. Evening temperature, 100.1° F. Pulse, 93. Characteristic typhoid roseola first appeared four days thereafter, on what was probably the eighth day. No Widal tests were made. No attempts were made to isolate typhoid bacilli from fæces or urine. Enlargement of spleen first detected on the twelfth day. Subsequent clinical course characteristic of typhoid fever.

Leucocyte counts made on day above indicated: Total count, 6,100. Differential count:

| | JENNER'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 9.2 per cent. | 12.8 per cent. |
| Large mononuclears.... | 28.1 " | 24.1 " |
| Polymorphonuclear neutrophilics..... | 59.9 " | 61.7 " |
| Eosinophiles..... | 2.8 " | 1.4 " |
| Basophilics (mast-cells). | 0.0 " | .... |
| | 100.0 per cent. | 100.0 per cent. |

CASE V.—A. H., aged nine years. Characteristic prodromal history of typhoid fever. Leucocyte counts made on what was probably the seventh day. Evening temperature, 102° F. Pulse, 97. Characteristic typhoid roseola appeared three days thereafter, on what was probably the tenth day. Widal reaction (1-20) first positive on the thirteenth day. A previous Widal test had been made on the seventh day. Typhoid bacilli were isolated from the fæces by the Hiss method at the first attempt on the tenth day, and from the urine at the first attempt on the twenty-third day. Urine contained albumin, but no casts.

Leucocyte counts made on day above indicated: Total count, 5,000. Differential count:

| | JENNER'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 11.6 per cent. | 14.2 per cent. |
| Large mononuclears.... | 24.2 " | 22.0 " |
| Polymorphonuclear neutrophilics..... | 63.5 " | 63.0 " |
| Eosinophiles..... | .7 " | .8 " |
| Basophilics (mast-cells). | 0.0 " | .... |
| | 100.0 per cent. | 100.0 per cent |

CASE VI.—M. A., aged twenty-six years. No prodromal history. Onset sudden. Leucocyte counts made on what was probably the fourth day. Evening temperature, 101° F. Pulse, 85. Characteristic typhoid roseola first appeared four days thereafter, on what was probably the eighth day. No Widal tests were made. No attempts were made to isolate typhoid bacilli from fæces or urine. Enlargement of spleen first detected on seventeenth day. Subsequent clinical course was typical of typhoid fever.

Leucocyte counts made on day above indicated: Total count, 4,750. Differential count:

| | JENNER'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 19.0 per cent. | 20.2 per cent. |
| Large mononuclears.... | 28.4 " | 29.3 " |
| Polymorphonuclear neutrophilics..... | 51.1 " | 49.1 " |
| Eosinophiles..... | 1.4 " | 1.4 " |
| Basophilics (mast-cells). | .1 " | 0.0 " |
| | 100.0 per cent. | 100.0 per cent. |

CASE VII.—J. E., aged six years. No prodromal history of typhoid fever. Leucocyte counts made on what was probably the third day. Evening temperature, 104° F. Pulse, 105. Characteristic typhoid roseola first appeared five days thereafter, on what was probably the eighth day. Widal reaction (1-40) first positive on the twelfth day. Previous Widal tests had been made on the third and eighth days. Typhoid bacilli first isolated from the fæces by the Hiss method on the fifteenth day. Similar isolation tests had been made on the eighth and twelfth days. No attempts were made to isolate typhoid bacilli from the urine.

Leucocyte counts made on day above indicated: Total count, 9,000. Differential count:

| | WRIGHT'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 21.2 per cent. | 21.0 per cent. |
| Large mononuclears.... | 26.3 " | 26.9 " |
| Polymorphonuclear neutrophilics..... | 50.1 " | 50.0 " |
| Eosinophiles..... | 2.4 " | 2.1 " |
| Basophilics (mast-cells). | 0.0 " | .... |
| | 100.0 per cent. | 100.0 per cent. |

CASE VIII.—H. W., aged eleven years. Indefinite prodromal history of typhoid fever. Leucocyte counts made on what was probably the fourth day. Evening temperature, 102.5° F. Pulse, 100. Characteristic typhoid roseola first appeared five days thereafter, on what was probably the tenth day. Widal reaction (1-40) first positive on the ninth day. A previous Widal test had been made on the fourth day. No attempts were made to isolate typhoid bacilli from the fæces or urine.

Leucocyte counts made on day above indicated: Total count, 6,000. Differential count:

| | WRIGHT'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 14.2 per cent. | 14.1 per cent. |
| Large mononuclears.... | 23.3 " | 23.1 " |
| Polymorphonuclear neutrophilics..... | 60.0 " | 60.4 " |
| Eosinophiles..... | 2.2 " | 2.4 " |
| Basophilics (mast-cells). | .3 " | .... |
| | 100.0 per cent. | 100.0 per cent. |

CASE IX.—N. H., aged fifteen years. Fairly characteristic prodromal history of typhoid fever. Leucocyte counts made on what was probably the sixth day. Evening temperature, 103.6° F. Pulse, 106. Characteristic typhoid roseola first appeared three days thereafter, on what was probably the ninth day. Widal reaction (1-40) first positive on the fifteenth day. Previous Widal tests had been

made on the sixth and tenth days. No attempts were made to isolate typhoid bacilli from fæces or urine.

Leucocyte counts on day above indicated: Total count, 5,500. Differential count:

| | WRIGHT'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 15.2 per cent. | 15.8 per cent. |
| Large mononuclears.... | 18.6 " | 18.7. " |
| Polymorphonuclear neutrophilics..... | 64.1 " | 64.5 " |
| Eosinophiles..... | 2.0 " | 1.0 " |
| Basophilics (mast-cells). | .1 " | .... |
| | 100.0 per cent. | 100.0 per cent. |

These nine cases show the following average percentages for the various leucocytes present. In computing the averages, I have utilized the counts made with Ehrlich's triacid stain. The averages from those made with Jenner's and Wright's stains show only a variance of a fraction of 1 per cent. from those computed from smears stained with Ehrlich's mixture:

| SMALL MONONUCLEARS. | LARGE MONONUCLEARS. | POLYMORPHONUCLEAR NEUTROPHILICS. | EOSINOPHILES |
|---|---|---|---|
| 17.8 per cent. | 21.1 per cent. | 59.4 per cent. | 1.7 per cent. |

The lowest and highest percentages for the various leucocytes are as follows:

| | SMALL MONONUCLEARS. | LARGE MONONUCLEARS. | POLYMORPHONUCLEAR NEUTROPHILICS. | EOSINOPHILES |
|---|---|---|---|---|
| Lowest— | 12.8 per cent. | 12.1 per cent. | 49.1 per cent. | .8 per cent. |
| Highest— | 22.8 per cent. | 29.3 " | 65.5 " | 3.0 " |

The remaining seven of the sixteen cases, from a consideration of the history and the clinical symptoms, I believe to have been within the first week when the leucocyte counts were made. I cannot, however, demonstrate beyond a reasonable doubt that such was the case. I hence include them in this report, but have not used them in computing the averages. The following is a detailed consideration of them:

CASE I.—M. B., aged eighteen years. Typical prodromal history of typhoid fever with epistaxis. Leucocyte counts were made on what was probably the sixth day. Evening temperature, 103.1° F. Pulse, 101. No characteristic typhoid roseola was ever observed. Widal reaction (1–20) first positive on what was probably the eighth day. A previous Widal test had been made on what was probably the sixth day. Typhoid bacilli were first isolated from the fæces by the Hiss method on what was probably the twelfth day. Typhoid bacilli were never isolated from the urine, although attempts were made by the same method on the twenty-first, thirtieth, and forty-first days.

Leucocyte counts made on day above indicated: Total count, 4,850. Differential count:

| | JENNER'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 14.5 per cent. | 16.2 per cent. |
| Large mononuclears.... | 21.1 " | 18.1 " |
| Polymorphonuclear neutrophilics..... | 62.3 " | 63.5 " |
| Eosinophiles..... | 2.0 " | 2.2 " |
| Basophilics (mast-cells). | .1 " | .... |
| | 100.0 per cent. | 100.0 per cent. |

CASE II.—A. W., aged twenty-seven years. No prodromal history. Leucocyte counts made on what was probably the third day. Evening temperature, 103.4° F. Pulse, 109. No characteristic typhoid roseola was ever observed.. Widal reaction (1–40) first positive on what was probably the tenth day. A previous Widal test had been made on the third day. No typhoid bacilli were ever isolated from the fæces, although attempts were made by the Hiss method on what were probably the third, tenth, twelfth, eighteenth, twenty-sixth, and thirty-fourth days. No typhoid bacilli were ever isolated from the urine, although attempts were made by the same method on the twenty-sixth and thirty-fourth days. The case ran a characteristic typhoid clinical course, with an enlarged spleen, and the Widal reaction (1–40) remained positive into convalescence.

Leucocyte counts made on day above indicated Total count, 5,700. Differential count:

| | JENNER'S STAIN. | EHRLICH'S TRIACID STAIN |
|---|---|---|
| Small mononuclears.... | 21.1 per cent. | 20.0 per cent |
| Large mononuclears.... | 25.2 " | 23.9 " |

CASE III.—E. M., aged twenty-two years. Characteristic prodromal history of typhoid fever. Leucocyte counts made on what was probably the fifth clinical day. Evening temperature, 102.2° F. Pulse, 100. Characteristic typhoid roseola first appeared two days thereafter, on what was probably the seventh day. Widal reaction (1–20) first positive on the twelfth day. Previous Widal tests had been made on the fifth and seventh days. Typhoid bacilli were isolated from the fæces by the Hiss method on the tenth day. Typhoid bacilli were never isolated from the urine, although attempts were made by the same method on the twenty-eighth, thirtieth, thirty-second, and thirty-eighth days.

Leucocyte counts made on day above indicated: Total count, 4,100. Differential count:

| | JENNER'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 8.2 per cent. | 9.1 per cent. |
| Large mononuclears.... | 32.4 " | 30.1 " |

| Eosinophiles..... | 1.7 " | 1.6 " |
| Basophilics (mast-cells) | .1 " | .... " |
| | 100.0 per cent. | 100.0 per cent. |

CASE IV.—D. P., aged seven years. Fairly characteristic prodromal typhoid history. Leucocyte counts made on what was probably the fifth day. Evening temperature, 101.3° F. Pulse, 108. No characteristic typhoid roseola was ever observed. Typhoid bacilli first isolated from the fæces on what was probably the sixth day, and from the urine on the thirty-second day. Widal reaction first positive (1–50) on what was probably the eighth day. A previous Widal test had been made on the fifth day. A complicating measles developed on what was probably the ninth day. Total leucocyte count on this day, 4,500. A differential leucocyte count on this day gave the following figures:

| | JENNER'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 9.8 per cent. | 8.9 per cent. |
| Large mononuclears.... | 3.2 " | 3.1 " |
| Polymorphonuclear neutrophilics..... | 86.1 " | 86.9 " |
| Eosinophiles..... | .9 " | 1.1 " |
| Basophilics (mast-cells). | 0.0 " | .... |
| | 100.0 per cent. | 100.0 per cent |

Leucocyte counts on day above indicated (the fifth): Total count, 6,750. Differential count:

| | JENNER'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 19.8 per cent. | 19.9 per cent. |
| Large mononuclears.... | 25.1 " | 25.7 " |
| Polymorphonuclear neutrophilics..... | 54.6 " | 53.7 " |
| Eosinophiles..... | .5 " | .7 " |
| Basophilics (mast-cells). | 0.0 " | .... |
| | 100.0 per cent. | 100.0 per cent. |

Case V.—F. H., aged thirty years. Indefinite prodromal typhoid history. Leucocyte counts made on what was probably the fifth day. Evening temperature, 102.9° F. Pulse, 100. Characteristic typhoid roseola first appeared two days thereafter, on what was probably the seventh day. Widal reaction (1–40) first positive on what was probably the twelfth day. A previous Widal test had been made on the fifth day. No attempts were made to isolate typhoid bacilli from the fæces. Typhoid bacilli were isolated from the urine by the Hiss method at the first attempt on the thirtieth day.

Leucocyte counts made on the day above indicated: Total count, 4,000. Differential count:

| | WRIGHT'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 16.2 per cent. | 16.7 per cent. |
| Large mononuclears.... | 31.1 " | 30.2 " |
| Polymorphonuclear neutrophilics..... | 50.1 " | 52.1 " |
| Eosinophiles..... | 2.3 " | 1.0 " |
| Basophilics (mast-cells). | .3 " | |
| | 100.0 per cent. | 100.0 per cent. |

Case VI.—M. M., aged twenty-one years. Indefinite prodromal typhoid history. Leucocyte counts made on what was probably the fifth day. Evening temperature, 103.5° F. Pulse, 112. No characteristic typhoid roseola was ever observed. Widal reaction (1–40) first positive on what was probably the fourteenth day. Previous Widal tests had been made on the fifth and eleventh days. No attempts were made to isolate typhoid bacilli from the fæces or urine. Subsequent clinical course was typical of typhoid fever.

Leucocyte counts made on day above indicated: Total count, 7,000. Differential count:

| | WRIGHT'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 10.1 per cent. | 10.2 per cent. |
| Large mononuclears.... | 24.9 " | 24.7 " |
| Polymorphonuclear neutrophilics..... | 63.9 " | 64.0 " |
| Eosinophiles..... | 1.0 " | 1.1 " |
| Basophilics (mast-cells). | .1 " | .... |
| | 100.0 per cent. | 100.0 per cent. |

Case VII.—E. S., aged fourteen years. Fairly characteristic prodromal history of typhoid fever. Leucocyte counts made on what was probably the fifth day. Evening temperature, 102.4° F. Pulse, 100. Characteristic typhoid roseola first appeared two days thereafter, on what was probably the seventh day. Widal reaction (1–20) first positive on the same day. A previous Widal test had been made on the fifth day. Typhoid bacilli were isolated from the fæces by the Hiss method at the first attempt on what was probably the eighth day. No attempts were made to isolate typhoid bacilli from the urine.

Leucocyte counts made on day above indicated: Total count, 5,750. Differential count:

| | WRIGHT'S STAIN. | EHRLICH'S TRIACID STAIN. |
|---|---|---|
| Small mononuclears.... | 19.0 per cent. | 19.2 per cent. |
| Large mononuclears.... | 18.9 " | 18.4 " |
| Polymorphonuclear neutrophilics..... | 60.1 " | 60.5 " |
| Eosinophiles..... | 1.9 " | 1.9 " |
| Basophilics (mast-cells). | .1 " | .... |
| | 100.0 per cent. | 100.0 per cent |

If the average figures for the various leucocytes in these seven cases are computed it will be found that they do not materially differ from the averages obtained in the nine cases which precede them.

*Summary.*—By comparing the figures found in the nine cases above referred to with those of Thayer in the first week, it will be at once seen that the relative number of polymorphonuclear neutrophilics is, in the average, much lower (14.6 per cent.), while that of the large mononuclears is much higher (8.7 per cent.). The small mononuclears and eosinophiles also show somewhat higher figures, but the marked decrease in polymorphonuclear neutrophilics is principally due to the marked increase in large mononuclears. My figures more nearly correspond, so far as the relative number of polymorphonuclear neutrophilics and eosinophiles is concerned, to those given by Winter, as found by him in ten cases during the second week, which are as follows:

| SMALL MONONUCLEARS. | LARGE MONONUCLEARS. | POLYMORPHONUCLEAR NEUTROPHILICS. | EOSINOPHILES |
|---|---|---|---|
| 5.8 per cent | 31.5 per cent. | 61.4 per cent. | 1.3 per cent |

In endeavoring to account for the marked variance between my figures and those of Thayer, it might be supposed that I had been in error in my differentiation between the large mononuclears and polymorphonuclear neutrophilics and had counted many cells among the former when in reality they should have been classified among the latter. This thought might carry weight provided these observations had been made upon the blood of a disease like diphtheria which we know from the valuable observations of Ewing in 1895 shows the presence of a large number of leucocytes which possess deficient staining properties, so that in the polymorphonuclear neutrophilics the neutrophilic granules are poorly stained and frequently almost entirely absent, while the protoplasm of the large mononuclears also stains faintly. It might be supposed that in examining stained smears of such a blood, the presence of such leucocytes would cause confusion to a man not familiar with Ewing's work, and lead him to misclassify large numbers of polymorphonuclear neutrophilics and large mononuclears. Now, as a matter of fact the blood of typhoid fever shows the presence of few, if any, such deficiently staining leucocytes, and all who have busied themselves with this line of work are agreed that the increase in large mononuclears, which is apparent to all during the middle and latter part of the disease, is principally, if not entirely, due to an increase in typical large mononuclear forms which could not be misclassified by any one who has had any experience in the examination of stained blood smears. I do not think, therefore, that in these observations I have made the error of classifying any polymorphonuclear neutrophilics among the large mononuclears. The only other supposition which could reasonably be advanced to account for the variance in these counts is that in reality my counts were made later in the disease than I claim. This point I have covered in a previous portion of this article, and I believe I have demonstrated, so far as it is possible, that my counts were made during the first week.

If my opinion be correct, the value of the differential in combination with the total leucocyte count in the early diagnosis of the disease, becomes a matter for serious consideration. I do not propose to enter into more than a preliminary consideration of this phase of the subject, because of the limited number of my observations. The acute diseases which usually show a normal total leucocyte count or a total hypoleucocytosis and which, so far as the total leucocyte count is concerned, would have to be differentiated from typhoid, are measles, influenza, pure tubercular infection and malaria. From a practical standpoint, however, only the latter two of these deserve consideration, since measles and influenza can easily be excluded upon a clinical

basis. With the differential leucocyte count in pure tubercular infection I have had no personal experience. So far as I am able to ascertain, there is but one case in literature. This is a case of acute miliary tuberculosis, and is cited by Cabot in the last edition of his work. Here the relative number of polymorphonuclear neutrophilics was 91.64 per cent. With the differential leucocyte count in malaria I have had a small experience (seventeen cases). The following are the total and differential counts found. In all of the cases, malarial organisms were abundantly present in the blood. The number of leucocytes counted was 1,000.

CASE I.—Tertian. Total count, 4,500. Differential count:

| | JENNER'S STAIN. |
|---|---|
| Small mononuclears | 13.2 per cent. |
| Large mononuclears | 32.4 " |
| Polymorphonuclear neutrophilics | 54.0 " |
| Eosinophiles | .4 " |
| Basophilics | .0 " |
| | 100.0 per cent. |

CASE II.—Tertian. Total count, 16,000. Differential count:

| | GOLDHORN'S STAIN. |
|---|---|
| Small mononuclears | 1.6 per cent. |
| Large mononuclears | 14.4 " |
| Polymorphonuclear neutrophilics | 84.0 " |
| Eosinophiles | 0.0 " |
| | 100.0 per cent. |

CASE III.—Tertian. Total count, 12,000. Differential count:

| | GOLDHORN'S STAIN. |
|---|---|
| Small mononuclears | 1.4 per cent. |
| Large mononuclears | 21.6 " |
| Polymorphonuclear neutrophilics | 77.0 " |
| Eosinophiles | 0.0 " |
| | 100.0 per cent. |

CASE IV.—Tertian. Total count, 5,000. Differential count:

| | GOLDHORN'S STAIN. |
|---|---|
| Small mononuclears | 5.0 per cent. |
| Large mononuclears | 18.1 " |
| Polymorphonuclear neutrophilics | 76.9 " |
| Eosinophiles | 0.0 " |
| | 100.0 per cent. |

CASE V. — Tertian. Total count, 7,000. Differential count:

| | WRIGHT'S STAIN. |
|---|---|
| Small mononuclears | 32.8 per cent. |
| Large mononuclears | 42.0 " |
| Polymorphonuclear neutrophilics | 25.0 " |
| Eosinophiles | .2 " |
| | 100.0 per cent. |

CASE VI.—Tertian. Total count, 6,000. Differential count:

| | EHRLICH'S TRIACID STAIN. |
|---|---|
| Small mononuclears | 32.4 per cent. |
| Large mononuclears | 19.0 " |
| Polymorphonuclear neutrophilics | 47.2 " |
| Eosinophiles | 1.4 " |
| | 100.0 per cent. |

(A blood smear made from the same patient at the same time and stained with Wright's stain showed a large number of malarial organisms.)

CASE VII.—Tertian. Total count, 7,000. Differential count:

| | WRIGHT'S STAIN. |
|---|---|
| Small mononuclears | 6.2 per cent. |
| Large mononuclears | 9.2 " |
| Polymorphonuclear neutrophilics | 84.4 " |
| Eosinophiles | 0.0 " |
| Basophilics (mast-cells) | .2 " |
| | 100.0 per cent. |

CASE VIII.—Tertian. Total count, 4,000. Differential count:

| | EHRLICH'S TRIACID STAIN. |
|---|---|
| Small mononuclears | 17.0 per cent. |
| Large mononuclears | 22.0 " |
| Polymorphonuclear neutrophilics | 60.5 " |
| Eosinophiles | .5 " |
| | 100.0 per cent. |

(A blood smear made from the same patient and at the same time and stained with Wright's stain, showed the abundant presence of malarial organisms.)

CASE IX.—Tertian. Total count, 4,000. Differential count:

| | WRIGHT'S STAIN. |
|---|---|
| Small mononuclears | 4.0 per cent. |
| Large mononuclears | 49.0 " |
| Polymorphonuclear neutrophilics | 47.0 " |
| Eosinophiles | 0.0 " |
| | 100.0 per cent. |

CASE X.—Tertian. Total count, 4,500. Differential count:

| | WRIGHT'S STAIN. |
|---|---|
| Small mononuclears | 2.0 per cent. |
| Large mononuclears | 35.0 " |
| Polymorphonuclear neutrophilics | 61.5 " |
| Eosinophiles | 1.5 " |
| | 100.0 per cent. |

CASE XI.—Tertian. Total count 11,000. Differential count:

| | WRIGHT'S STAIN. |
|---|---|
| Small mononuclears | 6.8 per cent. |
| Large mononuclears | 37.8 " |
| Polymorphonuclear neutrophilics | 52.2 " |
| Eosinophiles | 3.2 " |
| | 100.0 per cent. |

CASE XII.—Æstivo-autumnal. Total count, 4,000. Differential count:

| | WRIGHT'S STAIN. |
|---|---|
| Small mononuclears | 3.0 per cent. |
| Large mononuclears | 43 0 " |
| Polymorphonuclear neutrophilics | 52.5 " |
| Eosinophiles | 1.5 " |
| | 100.0 per cent. |

CASE XIII.—Æstivo-autumnal. Total count, 11,000. Differential count:

| | WRIGHT'S STAIN. |
|---|---|
| Small mononuclears | 10.0 per cent. |
| Large mononuclears | 15.8 " |
| Polymorphonuclear neutrophilics | 74.2 " |
| Eosinophiles | 0.0 " |
| | 100.0 per cent. |

CASE XIV.—Æstivo-autumnal. Total count, 6,500. Differential count:

| | WRIGHT'S STAIN. |
|---|---|
| Small mononuclears | 11.4 per cent. |
| Large mononuclears | 12.5 " |
| Polymorphonuclear neutrophilics | 75.3 " |
| Eosinophiles | .8 " |
| | 100.0 per cent. |

CASE XV.—Æstivo-autumnal. Total count, 7,000. Differential count:

| | WRIGHT'S STAIN. |
|---|---|
| Small mononuclears | 10.1 per cent. |
| Large mononuclears | 9.5 " |
| Polymorphonuclear neutrophilics | 80.0 " |
| Eosinophiles | .4 " |
| | 100.0 per cent. |

CASE XVI.—Æstivo-autumnal. Total count, 5,000. Differential count:

| | WRIGHT'S STAIN. |
|---|---|
| Small mononuclears | 8.6 per cent. |
| Large mononuclears | 15.4 " |
| Polymorphonuclear neutrophilics | 75.1 " |
| Eosinophiles | .9 " |
| | 100.0 per cent. |

CASE XVII.—Quartan. Total count, 6,000.

| Differential count: | WOOD'S STAIN. |
|---|---|
| Small mononuclears | 6.5 per cent. |
| Large mononuclears | 24.1 " |
| Polymorphonuclear neutrophilics | 69.3 " |
| Eosinophiles | .1 |
| | 100.0 per cent. |

From a consideration of the differential leucocyte counts present in these cases of malaria, it is at once seen that in many instances of this disease the differential count so closely simulates that present in many cases of typhoid during the first week that a separation is impossible. Certain of these cases of malaria (eight out of seventeen) show a marked relative increase in the polymorphonuclear neutrophilics, and hence could be easily differentiated from typhoid. By looking over them it will be seen that, as a rule, they show a much less relative number of eosinophiles than do the typhoid cases. These cases of malaria were all febrile cases, and the smears were made at the time they appeared for diagnosis. In them the relative number of eosinophiles was almost always below 1.5 per cent. and usually below 1 per cent., while the reverse holds true for the typhoid counts. Just how important a point this is in separating the differential counts of these diseases, I do not know. This point can only be determined by increased observations.

*Conclusions.*—1. Many cases of typhoid fever, contrary to general supposition, show the characteristic differential leucocyte count within the first week of the disease.

2. The definite value of the differential leucocyte count in the early diagnosis of typhoid fever is as yet problematical; but it seems certain that when used in addition to the total leucocyte count, more information may be obtained than by employing the total count alone.

In conclusion, it gives me pleasure to acknowledge my indebtedness to Prof. T. Mitchell Prudden and Dr. Francis C. Wood for valuable suggestions during this work.

**The Relation of the Islands of Langerhans to Diabetes Mellitus.**—Albert Ernest Finney concludes that (1) Diabetes may occur in the absence of any demonstrable lesion in the islands of Langerhans, and the glycosuria in such cases may be of nervous origin, or may correspond to the type described as "alimentary glycosuria." (2) Diabetes may occur accompanied by lesions of the islands, which, however, are not of sufficient extent to be in accordance with the results of Mehring's and Minkowski's experiments on extirpation of the pancreas. In such cases it is possible that the islands which present no anatomical lesion may have become functionally inactive. (3) Diminution in number of the islands in diabetes may occur in various proportions, even to total disappearance, and where such diminution is slight, its only importance is the inert, or retrogressive, condition of the islands which it implies. (4) Lesions of the islands may occur in the absence of diabetes, being in such cases of slight extent, and never of primary nature. (5) Diabetes may, lastly, be associated with lesions of the islands apparently primary, and even confined to the islands themselves. These consist in hyaline transformation, and specific necrobiosis.—*The Medical Chronicle.*

## A CASE OF LEUCOSARCOMA OF THE CHOROID.*

BY THOMAS R. POOLEY, M.D.
NEW YORK.

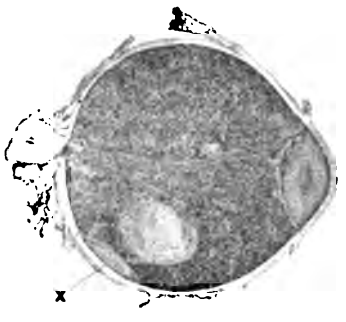
THIS case is reported because of the comparative rarity of non-pigmented sarcoma of the choroid, as well as on account of some points of interest in its clinical history and anatomical findings.

The patient, a man aged thirty-five years, came under my care on December 12, 1902, in my clinical practice. He was possessed of very limited intelligence and could give but little account of his symptoms. About three weeks before I saw him he thought he had gotten something in his left eye, and as his eye continued irritable, and he found that he could not see with it, he applied for treatment. He did not complain of severe pain in the eye at any time, and is sure that before the time referred to he saw very well with it.

When I examined him, this eye showed the typical features of absolute glaucoma: Circumcorneal injection of a venous character, hazy cornea, wide immovable pupil, shallow anterior chamber, anæsthesia of the cornea, T 3; entire absence of reflex with ophthalmoscope, and no perception of light. I made the diagnosis of absolute glaucoma, probably caused by tumor of the choroid, and thought enucleation should be done forthwith. Yielding, however, to the opinion of several of my colleagues, that it might be primary acute glaucoma, or due to a hemorrhage, I consented first to try iridectomy, which operation I did the same day. The operation, with the patient under ether, was successfully accomplished and resulted in a large coloboma; the anterior chamber, however, immediately filled with blood.

On December 14 there was some diminution in the tension of the eye, but hardly any absorption of the blood. By December 17, however, the blood in the anterior chamber was diminished, when, on the 18th, a fresh hemorrhage took place, nearly filling the anterior chamber and accompanied by pain and increase of tension. There was again an attempt by nature to absorb the blood, but fresh hemorrhage always took place, and, on January 3, 1903, I got the patient to consent to enucleation of the eye, which was done without any mishap, and, because of my belief that there was a tumor, I divided the optic nerve as far back in the orbit as I could. The healing was uneventful and the patient was discharged a few days later.

After being hardened in 10 per cent. formalin for a week, the eye was examined by Dr. Edward B. Coburn, pathologist of the New Amsterdam Eye and Ear Hospital, whose report is as follows:



From a photograph by Dr. Edward B. Coburn; dotted line (x) showing connection of the parts of the tumor by a narrow band.

"*Macroscopically.*—Shallow anterior chamber. Iris atrophic, with coloboma (from iridectomy) upward and adherent to the lens capsule. Lens appears swollen as though forced into the space

*Read before the American Ophthalmological Society at Washington.

of the coloboma. The retina is detached and extends like a flattened cord from the optic nerve to the posterior surface of the lens. One side of this retinal cord is attached to the apex of the tumor. The tumor lies between the detached retina and the sclera and arises from the choroid in its posterior temporal portion, about on a level with the external rectus muscle and just behind the equator. The tumor presents two parts—a flattened, somewhat extended portion, about 1 cm. wide and about 2 mm. high, connected by a narrow constricted portion, about 4 mm. wide, to a spherical part, about 7½ mm. high and 9 mm. wide, lying in the vitreous. The tumor is white in appearance, with only a few blood vessels and small pigment spots visible.

"*Microscopically.*—The conjuctiva is congested and slightly infiltrated. The cornea is apparently normal. The anterior chamber is practically abolished, only a small layer of bloodcells lying between the iris and the cornea. The iris is thin and atrophic. The angles of the anterior chamber are closed, the iris being adherent to the cornea at its periphery. The lens capsule shows pigment spots on its anterior surface. Beneath the capsule there is some albuminous fluid and there is a breaking down of the lens fibers in a few places, indicating an incipient cataractous change. The ciliary processes are attenuated and dragged forward with the lens, on one side being compressed between the lens and the iris.

"The retina is a flattened, cone-shaped mass extending from the optic nerve head to the posterior surface of the lens and continuing around to its attachment at the ora serrata. The retina is disorganized in the manner common to retinas detached in this manner.

"Only a small portion of the tumor appears in the sections, and that is taken from the side of the spherical portion lying in the vitreous. This consists of small round cells, with a slight amount of intercellular substance. The blood vessels which are small, have walls of a single layer of cells. A few pigment granules and pigmented cells appear in the peripheral portion of the tumor. The flattened part of the tumor between the lamina and vitrea and the sclera does not appear in the sections.

"*Diagnosis.*—Small, round-celled leucosarcoma of the choroid.

"*Remarks.*—The flattened part of the tumor is probably caused by the resistance of the lamina vitrea on the one side and the sclera on the other. At one point the lamina vitrea had yielded, and through the perforation the tumor has grown unrestricted in the vitreous, assuming the spherical form. The constriction is caused by the non-yielding character of the lamina vitrea as compared with the looser and less resistant character of the choroid and retina. The vitreous lies between the retina and the choroid, and an interesting question arises how the vitreous assumes this position—whether it is filtered through the gradually contracting and detached retina or whether it passes through a rent in the retina."

It is not my purpose to go into the literature of these tumors, for which I have neither time nor desire; I may, however, say that, according to Griffith, in his chapter on Diseases of the Choroid in the Norris-Oliver System, non-pigmented sarcoma is said to be more frequent in the younger patients, and in the middle or anterior parts of the choroid; which, so far as age is concerned, is confirmed by our case, but the growth developed from the posterior temporal portion of the choroid. The proportion of cases of leucosarcoma, according to the same author, is one for every ten or fifteen of the pigmented variety.

Although the case presented the usual appearance of final glaucoma, yet, according to the patient's statement, there had been only slight pain, not of the severe kind usually associated with acute glaucoma. When increase of tension exists with retinal detachment, with the eye in a state of acute glaucoma and there is no translucency, there need be no longer, as a rule, any hesitation in pronouncing the case one of choroidal tumor, and such, indeed, was my diagnosis, notwithstanding that I first made an iridectomy. That this course is open to criticism I freely admit, for, while iridectomy is strongly indicated in acute primary glaucoma, it is objectionable in choroidal sarcoma, because it delays the enucleation and may give rise to infection of the neighboring tissues. Griffith (*l.c.*) gives some important differential symptoms between glaucoma due to an intraocular growth and the primary form, *i.e.* the sight is lost for a considerable time before the acute symptoms set in, and further that the prodromi usual in primary glaucoma are often wanting. Another very important point in the differential diagnosis is that there are no remissions in the symptoms, such as we see in primary glaucoma. Retinal hemorrhage is sometimes quickly followed by glaucoma, and if this occurs with a large blood-clot may lead to an erroneous diagnosis. Such a case is recorded by Griffith (*l. c.*), and Webster reports a similar experience. It is interesting to observe, as suggested by the case reported, that the size of the tumor does not seem to be the most important factor in awakening a glaucomatous attack, but rather the changes to which it gives rise in the other tissues of the eye, especially of serous effusion, causing not only detachment of the retina but crowding it close to the posterior surface of the lens, the angles of the iris being obliterated and the iris adherent to the cornea at its periphery. This serous effusion seems to be an almost constant accompaniment of choroidal tumor.

107 Madison Avenue.

## THE RANGE OF OSTEOPLASTY AS AN AID IN THE CONSERVATIVE SURGERY OF BONE TRAUMATISM.

By THOMAS H. MANLEY, Ph.D., M.D.,
NEW YORK.

PROFESSOR OF SURGERY IN THE NEW YORK SCHOOL OF CLINICAL MEDICINE; VISITING SURGEON TO METROPOLITAN AND HARLEM HOSPITALS.

Osteoplasty may be utilized in the therapy of fractures, as a primary or secondary procedure, in fracture-dislocations, or in various dislocations alone; in open-fracture, as a primary measure, when there is displacement, shattering or loss of bone. Its widest range of application is when employed consecutively in deformities. In ankyloses and the pseudoarthroses, its great *forte* is as a substitute for amputation.

It sometimes occurs that, after the severe crushing of an extremity with multiple closed or open fractures, the degree of destruction of the part is so great that the most we are permitted with safety to accomplish is to make a diagnosis; the mangled parts present a dubious vitality, and all our efforts must be directed toward striving to preserve the limb, or any part of it, in any shape. Cases illustrating this class we most frequently witness after machinery or railroad accidents.

In several severe multiple fractures with extensive contusion and laceration of the deeper and vital structures, as the vascular trunks, we must be content to place the limb in such a position as will best relax the muscles, give comfort and secure the best functional results, quite irrespective of imperfect anatomical reconstruction of the osseous

parts. In many of these, deformities and impediment in function are quite certain to follow.

In large open fractures the collapsed state of the patient, from loss of blood or great violence, will compel us to desist from effecting an ideal toilet of the wound or from making such an adjustment of the fragments as modern surgical art requires. Our aim is in this instance to arrest hemorrhage, to cleanse and close in the parts as speedily as possible, and later, after recovery is complete, to correct any gross defect by secondary osteoplasty. There are many cases, however, in which primary osteoplastic methods are both expedient and imperative, before any sort of permanent adjustment is applied to the limb. The hemorrhage controlled, and the parts cleansed, the displaced fragments are reduced, and all those spicula of bone scrupulously replaced and preserved which retain any connective tissue or periosteal attachment. Those fragments which lie entirely free from any connections should be removed as they will later serve only as foreign bodies. If the fracture be of the leg—of the tibia and fibula, and the degree of overriding of the fragments be extensive and not to be overcome, we must not hesitate to divide the tendo Achillis and bring the separated bones into complete adjustment; but this extreme measure should never be resorted to until after three days at least, or until muscular relaxation has become well established.

Open fracture with loss of bone substance calls for various osteoplastic procedures in the way of grafting, autoplastic, homoplastic, and heteroplastic. Or all these may be dispensed with, by boldly contracting or shortening the limb. But few of these devices are possible immediately after fracture, or until reaction is fully re-established and all inflammatory action is subdued.

In the fracture of bone in children it is sometimes remarkable to note the speedy osseous regenerative action frequently witnessed after trauma or destructive pathological action; sometimes an entire bone shaft is restored after fracture, and quite invariably, when there has been extensive shattering of an articulation, regenerative processes may be so complete and perfect that impaired movement is seldom observed.

Juvenile fracture of the open variety generally promises much better results than similar fracture in the adult, provided only the circulation is ample, and is not unduly impeded by any sort of mechanical appliance in the course of treatment. We have here immature bones, their periosteal investment is thick and highly vascular, and besides regeneration of bone at the site of injury, we note its simultaneous physiological augmentation by normal growth. But the blood vessels of a child are easily strangled by firm adjustments after fracture; a limb primarily promising well soon may become cold, pulseless, and asphyxiated.

In open fracture of children, if fragments of the shaft have been shelled out of the periosteum, there is no use of attempting to replace them, for the reason that their fusion will quite certainly fail, and besides, with the periosteum intact, the limb placed in a comfortable position, full regeneration may be expected. In order to avoid sloughing or dangerous asphyxia in children, it is necessary that the dressings be frequently changed and that the adjustment be rather a *support* than a fixation, at least until ossific repair be well advanced.

*Secondary osteoplasty* has a very wide range of application for those deformities or anatomical defects which follow various serious fractures, generally from causes inherent to the injury itself; for a deplorable class of cases, for which in the near past little or nothing could be done; many of the afflicted having been compelled to carry crippled useless limbs for their life-time, or have them amputated. Bilguer, the surgeon-general under Frederick the Great, who is recorded in surgical history as hostile to primary amputation for gunshot injuries of bone shafts, was severely criticised for this practice because after the wars so many crippled veterans were scattered throughout Prussia. In those days the acme of conservatism in surgery was reached when the maimed limb was spared in any shape; but now, thanks to the marvellous advances in surgical art, we go a step further and restore function to a wasted, painful, or deformed member.

Here osteorection, osteoclasis, osteotomy, ostectomy, with all the various resources of oteoplastic grafting, come into use.

In order that we may estimate the relative value of these resources, it may be well to set forth briefly the degree of utility of each at various stages after bones are broken.

*Osteorection.*—This implies the bloodless correction of a deformity or deflection of a broken bone shaft in its plastic, flexible stages of repair, before ossific consolidation is complete. In order to derive the best effects from this valuable and simple expedient, we must see to it that the mechanical adjustments are frequently changed, as sometimes the fragments ossify with surprising rapidity.

Usually from the third to the fifth week is the best period to take advantage of it; but in growing children, earlier; however, it has been successfully availed of by myself even as late as the third month. During the plastic stages of repair, as the parts are more or less sensitive, it may be well to employ an anæsthetic; in many, however, but little pain is felt, while the unaided hand presses the distorted member into line.

After full correction the limb must be placed in an unyielding fixation apparatus until consolidation is complete. If there be a large provisonal callus, and it be the lower extremity which is involved, a supporting brace must be worn until this has resorbed.

I am confident that this simple expedient is not sufficiently frequently utilized, and neglect of it may involve one in a troublesome litigation, or leave a deformity, always easily corrected in the early stages of osseous repair.

The conditions most commonly calling for osteorection are constitutional, often producing "delayed union." Syphilis, strumor, or malaria is often evidence, therefore systemic influence should not be overlooked during treatment.

*Osteoclasis.*—The refracture of bone shafts after vicious union or deformity is a very ancient expedient, though it was very rarely resorted to in preanæsthetic times. It is now seldom utilized, except in orthopedic surgery, when an osteoclast is employed, for the rickety deformities of the limbs in early childhood. Osteoclasis alone is now rarely resorted to, to induce refracture for deformity. Although the callous bond uniting broken bones is wanting in the typical anatomical structure of the normal, it often offers greater resistance to force, and hence the shaft will yield to violence rather above than below, directly through the callus. Moreover, in any event, it not infrequently happens that the force necessary to employ, produces an extensive contusion and laceration of the adja-

cent soft parts. It will be therefore only in exceptional instances that we will resort to refracture by force alone, except with the smaller shafts in childhood, or when calcification at the junction of the fragments is incomplete. Manual osteoclasis frequently serves an admirable purpose in the deflections following in the fractured shafts of early childhood or even later, as it obviates the necessity of dividing the tissues; in this class it should generally be resorted to.

*Osteotomy* alone, or combined with osteorection—The complete, or more frequently the incomplete, division of a bone shaft in the treatment of osseous deformities, traumatic or pathological, is undoubtedly one of the most valuable expedients of modern surgery. In the correction of deformities following fracture, we utilize it as an accessory to force. In every instance we produce an open fracture, something greatly to be dreaded in pre-antiseptic times, or before, or before McEwen of Glasgow demonstrated the harmlessness of this complication. Osteotomy, however, is a more serious undertaking when employed to correct deformities after fracture than when utilized to correct the bowing of the limbs from rickets.

In the former there is nearly always a hyperostosis, the callus often being of marked density and without proper periosteal envelope has acquired extensive and very intimate adhesions with the sheath of large blood trunks, the nerves and muscles; hence in the division of the thick uniting bond, caution must be observed not to encroach unduly on these structures. We never quite completely divide the shaft through, but having penetrated through about one-half or more of the circumference of the cortical layer, we complete the refracture by the use of intelligently applied force.

When there are two parallel bone shafts, as those of the leg or the forearm, osteotomy may be applied to the largest shaft only. It is my experience, however, that it is most expedient and induces less traumatism to employ the osteotome in both shafts, especially when the point for clearage is so located that the shafts lie near the surface.

Osteotomy for the deformity following fracture has been repeatedly employed by myself on all the shafts of the extremities. In children caution must be observed to keep clear of the epiphyseal junction. In no single instance has any serious consequence followed. Union has in all cases been as rapid and complete as in any similar closed fracture.

It is my conviction that the field for osteotomy is certain to expand greatly, and that in the near future it will be largely utilized in Colles, in Potts, and several other fractures which are contiguous with or involve the articulations and which are so often followed by impediments in function or deformity.

*Osteectomy* or resection of sound bone is sometimes called for in defects following fracture, or when, as with the parallel shafts, there has been a fracture with loss of bone substance in one shaft, while the other remains entire; a condition most frequently found in certain gun fractures through the tibia.

*Resection of Bone.*—In osteoporosis or hyerostosis with deformity following fractures of the femur or the humerus, we are sometimes compelled to clear away all the morbid bone callus before we can bring into correct apposition their healthy surfaces.

At present resection of bone is very rarely necessary as a primary procedure after open fracture. There is very seldom any description of open fracture, however great the displacement that permits of any sacrifice of sound bone. In pre-antiseptic times, when the sharp projecting side of the bones penetrated through the integument, if much resistance was offered in attempts at reduction it was the custom to cut them off with a pliers or saw. But now, by embalming and delay until muscular spasm passes away, they are usually easily reduced. If this fail we may do a tenotomy or freely enlarge the opening and replace the fragments.

These fractures are always oblique, a variety, though usually difficult to adjust, unite more quickly than the transverse, because, as Senn correctly states, there is a larger area of ossific regeneration called into activity.

## SOME OF THE MISTAKES WE HAVE INHERITED.

By MARK I. KNAPP, M.D.,
NEW YORK.

With the above caption I shall endeavor to bring before the profession our inherited mistakes concerning the interpretation of (1) vomiting; (2) of appetite; (3) the eating of stale bread; (4) of eating sugars and fruit for their laxative effect.

Vomiting is a symptom of great significance, be it primarily due to the stomach or not. Textbooks lay great stress on vomiting when it ushers in the disease, and attempt to attribute to such vomiting diagnostic value. This latter is manifestly wrong. Vomiting is no more diagnostic of scarlet fever, or of cerebrospinal meningitis, than is the pain of osteomyelitis or the headache of typhoid fever. That vomiting occurs in diseases other than those of the stomach is true, but the vomiting itself, *per se*, is due to a simultaneous, palpable, concrete cause operating on the stomach. To this there is scarcely any exception. We might possibly produce vomiting by irritation of the vomiting center in the medulla, but this is laboratory experiment only. If there really exists vomiting due only to cerebral causes, such causes are few, and, in reflex vomiting, as in reflexes in general, I am not an over-enthusiastic believer. True it is that apparently there is no cause discoverable in many instances of vomiting, but this is due only to the fact that we do not look in the right direction. Let us impress this upon our mind that the phenomena of health and disease cannot (at least not as yet) be demonstrated by the dissector's knife, or by the microscope. These phenomena are chemical in their nature, and it is to chemistry we must look for the cause of the vomiting in every case. Have the physicians been making chemical analyses of the gastric contents in every case of vomiting? And yet, it would appear to the unbiased mind that one ought to look for the culprit in the premises whence emanates the mischief before going outside. But, chemical analyses often require a great deal of time, labor, and knowledge; on the other hand, the pronunciation of the term "reflex"—well. . . . If we but thought of the simplicity of the mechanism of vomiting we surely would have much less of reflex vomiting. The mechanism of vomiting is simplicity itself. Spastic. violent contraction of the stomach wall, during which the pylorus is closed and the cardiac opening open, expels the stomach contents through œsophagus and mouth to the external world. Nay, the stomach may even be entirely guiltless and the vomiting may proceed from beyond it, from the intestine. But in this latter case neither of the stomach openings is closed. Whenever there is violent contraction of the stomach or of the intestine (the pylorus being open in the latter case) vomiting is very apt to occur. When-

ever there are present in the first part of the alimentary canal bodies—solid, fluid or gaseous—which are irritating to the mucous membranes there occurs violent contraction, vomiting. Some individuals do produce vomiting at will. But the stomachs of such patients are never healthy, they always harbor irritating matter. Vomiting is also produced by tickling the fauces, or by putting one's finger into his mouth; these causes appear to act reflexly. However, by putting in of one's finger, the epiglottis is closed, and air rushes into the stomach. This distension produces the vomiting.

The vomiting produced in scarlet fever, in the passing of biliary or renal calculi, in tumors occurring in the abdominal cavity, the vomiting occurring in displacements of abdominal or pelvic organs—such vomiting is not due to reflexes. It is due to the direct, co-existing irritation in the alimentary canal. Anything pressing upon the intestine hinders or absolutely obstructs the passage of its contents. The consequence is, chemical changes, with the accompanying production of noxious, irritating bodies. which cause violent contraction of the walls of the intestines, expelling their contents or the contents of the stomach. We can then understand how tumors or displaced organs, which, compressing the lumen of the intestines, may produce vomiting, and, how after correcting such anomaly the vomiting stops. But the direct cause of the vomiting is in every case the direct noxious action upon the mucous membrane of the alimentary canal. The vomiting of pregnancy, undoubtedly, belongs to the same category.

In the presence of vomiting, as a symptom, we naturally inquire after the character of the vomit, and particularly after its color. Two colors have especially imprinted themselves upon the minds of all—lay and medical—I refer to the green and red vomit. The teaching has come down to us from our ancestors that the green vomit means bile, and that the red vomit means blood. There is some justification for the latter acceptance; the vomit is red and so is blood—due latitude being given to the shade of the color. But why the green vomit should be interpreted as meaning bile, I could not trace. The color of bile is not green, but a golden yellow. The very word "gall" means yellow, and is derived from the older latin word "giallus," yellow; in Italian "giallo." How often do patients complain of green vomit. This surely is not a rarity. In my paper on "Some New Facts in the Chemistry of the Stomach."[1] I have called attention to the fact that the green color of the chyme is due to the growth in the stomach of a green mold; very often such green mold is aspirated in very large patches. In such cases I had many times applied the Gmelin and Pettenkoffer tests, but could get no bile reaction. Kühne[2] subsequently also found that the green color did not mean bile, and my statement has since been corroborated by other gentlemen. So much for the green mold.

Due to the growth of large quantities of red mold in the stomach is very often its chocolate-brown-colored contents. Unfortunately, the chocolate-colored contents are always regarded as blood. I have already described cases[3] in which chocolate-colored contents were aspirated, and in which no blood whatsoever was found. Dark red streaks, variable in quantity, I very often see in the chyme. Whenever such red molds are present in appreciable quantity the accompanying symptoms are always rather severe. We therefore must *never assume the presence of blood;* if blood is suspected, its presence must be proven beyond any doubt with the assistance of chemistry and the microscope. Chocolate-brown vomit, alkaline in reaction, would point to the presence of blood and, if acid, to the presence of mold; however, both may coexist. Perfect assurance is absolutely necessary. The scientific, true physician must assume nothing; certainty must ever be his watchword. To attain the perfection of making an absolutely correct diagnosis in the disease of any organ is a gift one can be proud of, although, very often, the exact diagnosis offers little more than evidence of erudition and studious observation. Here, however, the exact diagnosis is all important. To mistake mold growth, gastrosia fungosa,[4] for gastric hemorrhage and *vice versa*, may be fraught with serious consequences, though mold growth is not incompatible with cancer or ulcus. For the diagnosis of mold growth in the stomach, a disease which affects the human race (undoubtedly animals as well) by the hundred thousands, I refer to my published articles: Organacidia gastrica;[4] gastrosia fungosa[5], and "additional note on organacidia gastrica."[6]

Let me again call attention that vomiting, unless induced voluntarily by the individual himself, is always produced (with possibly very rare exceptions) by the direct irritation of the mucous membrane of the alimentary canal, that it never is of reflex origin, that the cause for such vomiting lies always *within* the lumen of the alimentary canal, no matter what outside cause is responsible for it; that such causes need not be revealed by the microscope; that such causes will be evident on proper chemical analysis. Let us remember that green vomit, in by far the greatest majority of cases, does not mean bile, but the growth of the green mold, and that chocolate-colored vomit need not necessarily mean blood, that chocolate-colored vomit may mean the growth of red mold. Of course, green mold may coexist with bile, and red mold with blood.

A good, hearty appetite is something, the individual possessing it, mentions with gratification and pride. "I am always hungry"; "I could eat more but I am afraid;" "I have never enough," are sentences, which to express, rejoices the person who utters them. The degree of hunger is usually accepted as the standard of measure for the digestive ability of one's stomach. If one is always "good and hungry," if he has a "ravenous appetite," if he "can eat up a horse" the patient has proof evidence of the perfectness of his digestion. The occasional or possibly quite oft occurring spasms or cramps are to such an individual puzzling, and are apt to be attributed to anything else rather than impeach the integrity of an organ he is so proud of. Attendant headaches are easily explained away as due to almost anything; flashes of heat and cold surely denote malaria; the very occasional spell of vomiting is piously blessed, as it surely served to relieve the overloaded stomach, and consequently did good. The patient goes along this way for months, or even years, dieting himself a little while after each attack, and looking upon such attacks as irrelevant, annoying, and uncalled-for interruptions of his good appetite, and begrudging the time lost in dieting. The ringing of these occasional alarm bells is misinterpreted and the "excellent appetite" is accepted as the most convincing proof of perfect digestion. Having misunderstood those danger signals, the patient finally finds himself at a loss to explain the reason for his bad stomach. Such an "excellent," "ravenous" appetite is pathological; such an appetite is but one degree removed from pain. Very often the patients describe such an appetite as a painful appetite, *i. e.* they feel actual pain unless they immediately eat. Such an appetite is a false,

a pathological appetite, which the physician must suppress. The cause of such an appetite is the presence in the stomach of large quantities of organic acids. The organic acids are either introduced into, or are generated within, the stomach. These volatile acids irritate the mucous membrane, the response to which is contraction of the muscular coat. This contraction is commensurate with the irritation. The greater the irritation, the greater the contraction, the greater is the sensation, which in lesser degrees, is interpreted as hunger. Hunger, as already stated, I believe to be a lesser degree of pain, which, we have learned, is appeased by the introduction of food into the stomach. This theory is evidently corroborated by the declaration of the patient who describes his hunger as being of a gnawing, painful type, and that even headaches are apt to appear unless food is taken (for the direct connection of headaches with the condition of the stomach see the article mentioned above[5]). Assuming this theory to be correct, we can easily see the reason why men can fast for prolonged periods with, as they assert, no inconvenience whatsoever. The explanation would be this: The contraction of the stomach produces the painful sensation, the hunger. But as this contraction is after some time followed by relaxation, consequently the absence of the contraction means the absence of hunger. Here, again, the clinical history of the patient serves to corroborate this theory. Patients come to us with the history of previously having had an excellent appetite, but now the appetite is quite evanescent; unless they eat immediately they very soon lose their appetite. That is: the constantly insulted stomach gradually weakens and does no more respond with prolonged contraction. The contraction then very soon gives way to relaxation, hence the evanescent appetite. This mistakenly "excellent appetite" is a symptom of a pathological condition, and is likewise due to the presence within the stomach of organic acids, to organacidia gastrica.

Stale bread has evidently come down to us as a sort of medical incongruity. We always advise fresh food, but with bread we found it best to turn things upside down for once. What is the reason? Dyspeptics often suffer after eating fresh bread, but why? Fresh bread has always been an eyesore to the dyspeptic, not because he did not like it, but because he did like it, and was not allowed to eat it. Clinical experience, however, does teach that the patients, very often, positively do suffer after eating fresh bread. But, if it is true that some suffer after eating fresh bread, it is not proven that stale bread is harmless. In fact, the very contrary obtains. It is not the freshness of the bread that harms; it is not the quality, but it is the quantity of the fresh bread that is consumed. Fresh bread tastes good, is appetizing, and the consequence is that because of this a much larger, and excessive quantity is eaten. It is this excessive quantity that harms, not the freshness of the bread. On the other hand, the staler the bread the sourer it is, the more unappetizing it is and much less is eaten of it. I insist upon my patients eating the fresh bread, explaining to them the difference between the stale and the fresh bread, and never saw any trouble. How grateful are the patients after such advice.

What is true of fresh bread is true of potatoes. A well-boiled potatoe is delicious, and here again it is the quantity not the quality. A well-boiled, mealy potato is really a temptation, which but few can withstand.

Constipation is a question of great importance. I shall not enter here into the causes of an organic nature, but will confine myself to the constipation due to dietetic causes. These are either an insufficient imbibition of water, or the ingestion of constipating articles, or both. The first cause is easily elicited. As the second cause operates ingestion of too much starchy food, or imbibition of too much tanning containing articles, such as red wine, tea, and coffee. To remedy such constipation, we have inherited from our thoughtful ancestors the teaching to eat plenty of fruits, sweets, bread baked with the husks of the grain, whole grain bread, to drink sour milk, etc. That these produce emptying of the bowels cannot be denied. But whether it is rational to advise such a diet is very questionable. I never do advise it and have no regrets for my treatment. Let us think how are movements of the bowels produced. This is very simple. The fecal matter is propelled toward the anus. Assuming the presence of fecal matter within the intestines, and assuming that there are no obstructions to the lumen of the intestines, either from within or without, the fæces are propelled by the contraction of the muscular coats of the intestine. There is no dissenting voice to this. But what brings about the contraction of the intestinal wall? Contraction of the intestinal wall is excited by chemicals which are present within the lumen of the intestine. As a rule these chemicals belong to the lower series of the saturated hydrocarbons, which are in a gaseous state. The presence within the intestine of marsh gas, of acetic and of butyric acids is well known. But there are present also other irritating gases. Whether the presence of such irritating chemicals is absolutely necessary to excite peristalsis appeals to me to require a positive reply. The larger the quantity of such irritating chemicals or the more irritating they are, the stronger the peristalsis. Consequently, the ingestion of such food, which either contains irritating chemicals as their natural constituents, or which favor the production of irritating chemicals within the intestines, or the ingestion of such food which contains constituents that are easily broken up and transformed into irritating gases, such food does favor peristalsis. If too much of such food is taken, the peristalsis will be correspondingly larger, more active, more violent. Sugars are easily converted into the volatile acids of the paraffin series, and the husks of cereals are easily fermented; such fermenting again producing the volatile acids. Fruits contain a good quantity of ready acids besides sugar which is convertible into such acids. Consequently, the ingestion of such food will help to produce peristalsis. The administration of fruits, of stewed fruits, of honey or other sugars, of whole grain, bread, etc., for constipation is well known. But is such medication proper? The administration of sugars and of fruits is not to be advised, as, once recommended, they are taken in excess; and what might do good if taken in small quantities becomes absolutely dangerous when taken in large quantities. Sugars and fruits, by their conversion into organic acids, become decidedly injurious, if indulged in freely, giving cause to the conditions of organacidia gastrica (already mentioned) and organacidia enterica, which I shall soon describe.

## EARLY SYMPTOMS OF DEMENTIA PRÆCOX.*

By A. R. DIEFENDORF, M.D.,
MIDDLETOWN, CONN.
LECTURER IN PSYCHIATRY, YALE UNIVERSITY MEDICAL SCHOOL.

DEMENTIA PRÆCOX is one of the most prominent forms of mental disease, constituting over 25 per cent. of the insane of Connecticut, committed to the State Hospital during the past four years. It should also be of the greatest interest to the general practitioner because of the gradual and often insidious character of its onset, which places its subjects in his hands long before necessity seems to demand the care of a hospital. During this period the disease is often unrecognized and untreated.

It is essentially a disease of youth and early adult life, and is characterized by a progressive mental deterioration leading to dementia of different grades, varying from a very moderate degree to the most profound. The disease process when well established is usually recognized without difficulty. At this time hallucinations of hearing are especially prominent, consciousness is usually not clouded, although most patients do show some difficulty in comprehension. The power of attention is undermined by an increasing lack of interest. Memory shows a progressive impairment. The store of ideas becomes more and more scanty, and thought more limited. Judgment is defective, as shown by the presence of delusions, which at the beginning are more often of a depressing nature, but later may become expansive. These disturbances of the intellectual side of the mental life are usually accompanied by emotional deterioration —emotional apathy and indifference. Temporarily there may be considerable despondency or exhilaration, as well as irritability, when hallucinations and delusions are very numerous, but the fundamental alteration is a progressive emotional indifference. Volition becomes gradually paralyzed, and we find the patients exhibiting an increasing lack of energy. They are sluggish and listless. Transiently, there may appear restlessness or agitation, and even considerable motor excitement, also peculiarly modified movements called mannerisms. Catalepsy and negativism may occur, but here also the basic change is an increasing anergia.

This, in a general way, characterizes the disease picture of dementia præcox, but clinically the cases appear in one of three groups, the hebephrenic, the catatonic, and the paranoid. The peculiar symptoms constituting these various forms will not be discussed here, but our observations will be limited to the early symptoms which are practically the same for all of these different forms.

These early symptoms may be conveniently grouped into four different classes; namely, cases in which there is simple mental deterioration without hallucinations or delusions, cases in which a few indefinite delusions appear, cases of a neurasthenic character, and finally those of an hysteroid character. These can be best demonstrated by illustrative cases.

*Simple Mental Deterioration without Hallucinations or Delusions.*—The first patient is a young man of excellent family history. He developed normally as a boy and was of a cheerful, happy disposition. He was a good student and graduated with honors from high school. Nothing of an unusual character was noted until after his graduation, when a change in disposition came over him. At this time he failed to show any interest in the further pursuit of his education, or in adopting a profession. Instead he remained about home and, contrary to his usual custom, did not even aid his parents in the farm duties. Pampered by his mother, he was allowed to devote his time to social life, of which he had always been very fond, but in the course of six months he wearied of this and began to drop his friends. He remained at home, secluded himself in his room much of the time, occasionally reading pictorial newspapers, but more often sitting unoccupied in a sort of dreamy mood. Formerly his wearing apparel and his personal appearance had been matters of great pride with him, but now he became careless in these respects, and went about with disheveled hair and unpolished boots. Social obligations and church relations no longer interested him. Acquaintances and strangers calling at the house were avoided. Later financial difficulties of his father, and subsequent fatal illness, did not arouse him to a sense of responsibility. He no longer read, and never volunteered conversation, while his answers to questions were monosyllabic, clearly indicating his total disinterest in what was transpiring about him. Some months later, when thrown upon the charity of his sister at the death of his father, he could not be induced to do any sort of work. When urged he usually became irritable, and retaliated by saying he would show them that he did not have to work. Most of his time was spent sitting behind the kitchen stove. He showed absolutely no interest in the affairs of the household; occasionally when sent to the shed for wood, he would be found half an hour later standing idly against the side of the building. During the succeeding six months he became more careless of his appearance; refused to bathe, to have his hair cut, and at times to remove his clothing upon retiring at night. At this time the patient was committed to our care, when it was ascertained that the disease was already far advanced. The memory for both recent and remote events was greatly impaired, judgment was weak, emotional deterioration extreme, and paralysis of the will-power marked.

This is a case of dementia præcox in which the onset was most insidious, and the course progressive, leading to dementia before friends and acquaintances were aware of the existence of any disease process, or of the necessity of medical consultation and treatment. Because of the absence of hallucinations and delusions, the *sine qua non* of mental disease in the minds of most practitioners, cases of this sort are progressing to dementia in many communities of the State unrecognized and untreated. A considerable number of the so-called professional tramps as well as alcoholics, are really individuals suffering from this disease, destined sooner or later to reach the insane hospital.

*Cases with a Few Indefinite Delusions.*—The second class of cases is characterized by a gradual development of dementia accompanied by a few indefinite delusions, and is illustrated by the following case: This patient is a well-developed girl whose grandmother had been insane. In early childhood she had had scarlet fever with an abscess on her neck, followed by double otitis media purulenta, which still persists. Menstruation began at eleven years, had usually been excessive, but at times, from fourteen years, very scanty. Her teachers claimed that she was backward in her studies, but applied herself well to her work. In disposition she was quiet and bashful.

At sixteen it became evident to her parents that she was undergoing a change in disposition. She became more reserved, and preferred remaining alone in her room while studying evenings. She lost weight, seemed languid and had no relish for

*Read at the annual meeting of the Connecticut Medical Society, Hartford.

food. She confessed to her mother that she was worrying greatly about a leucorrhœal discharge. She thought that it was a bad disease, that her teacher also had it and had gotten it from her. Because of her physical condition it seemed best for her to remain out of school for the remaining two months of the school year. This change was immediately beneficial and she improved in weight and appetite, and appeared less reserved. But still her former energy was lacking and she failed to show her usual interest in the household duties. In the fall she could not be induced to return to school, as she felt that the teachers and scholars had turned against her. About this time she would often return from the neighbors, saying that she thought they had acted strangely toward her and did not want her to call on them. She was aware that a change was coming over her, and said that she longed to experience religion and wanted to be good, but something seemed to prevent her. She cried a great deal, especially when attending church. She tried to pray but could not. Conscious of her peculiar actions she wanted to unburden her heart to her mother, but felt as if she could not. Her attitude was one of despondency, and she became more seclusive and reticent. Physically, nutrition became impaired, the weight fell, constipation and anorexia appeared. In the course of three more months irritability and a tendency to impulsive actions developed. Once she threw dishes upon the floor, at another time a lamp, and finally broke out window panes without other reason than that she felt like it. These acts led to her commitment to the hospital. It is unnecessary to follow through her history at the hospital where further symptoms of the disease have developed.

A case of a similar sort, in which the symptoms were of a more insidious character and in which the delusional ideas and impulsive actions were of a more serious nature, is as follows:

The patient is a young man of good parentage, who had always enjoyed excellent health. The first change was noted at twenty-eight. At this time he began to have trouble with patrons, lacked his usual civility in responding to minor complaints, and was surly. His duties at times were indifferently performed and some irregularities were noted. Old friends were dropped, and instead of going to the club evenings, he would walk through the main street alone and then return home to lie on the sofa or sit alone in his room. He ceased attending church and often argued against his religion. Unintentional annoyances by others while at work were taken as purposeful hindrances, and at times led to hot words. At home he could not tolerate jokes, but became angry and even profane with his sisters. He would not brook interference or tolerate any suggestions from his younger brother, by whom he thought he was being supplanted. The family, unaware of the pathological character of these manifestations, did taunt him rather more than usual, while the male members of the family coped with his surliness by administering one or more punishments. This behavior on their part gave rise to the idea that the family intended to force him to leave home. Following this he became still more sullen and resentful, and finally armed himself for an anticipated assault. Some months later, when reproved by his parents for the use of profanity in the presence of his sisters and ordered to leave the house, he shot and injured both his father and brother. Fortunately, this patient fell into the hands of two physicians who had had special training, and his disease was clearly recognized, so that he was sent to the hospital, where close examination corroborated their diagnosis of beginning dementia præcox

It is not at all unusual that cases of dementia præcox, as the result of persecutory delusions, come in conflict with the law. Unrecognized by the medical and legal profession, most of these cases are subjected to the hardships of penal institutions instead of treatment in institutions provided for their care. During the past five years the majority of the youthful cases sent to our institution from the States' prison and jails, have been suffering from this form of disease, whose early symptoms must have been in evidence at the time of the commitment of their crime.

*Neurasthenic Cases.*—The third class of cases is represented by the following: The patient is a young man of good family without neurotic taint, except that his father had been intemperate and immoral, and there had been a history of tuberculosis on both sides of the family. He had passed through an uneventful boyhood, had been a good student, and after graduation had been successfully employed as a bookkeeper. From the ages of sixteen to eighteen he had been addicted to moderate masturbation, and also had been moderately intemperate. At nineteen, following an attack of gonorrhœa which had subsided into gleet, he presented a gradual change of character, first noted by his parents during his annual vacation at home. He displayed no interest in family affairs, but remained alone and seemed to be self-absorbed and suspicious. Unbeknown to his parents he was reading quack literature, and had consulted several physicians of the same order in reference to his trouble. He conceived the idea that the use of metallic sounds had forced the disease backward into the deeper parts, where it had communicated with the spinal column and was undermining his health by allowing the escape of the "vital fluid." This accounted for his various neurasthenic symptoms, such as pains in the head, dizziness, peculiar sensations in the limbs, as well as increased sense of fatigue. As objective symptoms he presented impaired nutrition, loss of weight, increased reflexes, and vasomotor disturbances. Self-absorption increased and his sole topic of conversation was in reference to his somatic disorders. He soon returned to his work, which he could follow with only indifferent success. He would frequently absent himself from his work, and would be found standing alone in the basement of the store, gazing vacantly before him. His incompetency increased and led to his discharge six months later. For the two succeeding years he remained about home, idling away his time. Meanwhile his hypochondriacal ideas of a sexual nature gradually faded and somatic delusions of a pronounced character took their place. He also expressed delusions of influence, and said that he was being hypnotized and that others could read his thoughts. Deterioration of memory and judgment advanced, and impulsive acts and silly laughter occasionally appeared. At the time of his commitment to the hospital at the end of this period the disease was already far advanced.

Such cases at the onset are naturally regarded by most practitioners as cases of neurasthenia. While it must be admitted that sometimes the distinction between neurasthenia and dementia præcox at the onset is not easy, yet most cases of the latter disease can be detected. In neurasthenia there is always present an adequate cause for the asthenic state of the nervous system. This is rarely present in dementia præcox. The emo-

tional attitude of the neurastheniac is very different from that of the dementia præcox patient. In neurasthenia there is usually some despondency, also apprehension for the outcome of the disease, but this emotional condition regularly varies, and the patients have their hopeful days, when they are cheerful and buoyant. Neurastheniacs regularly improve as the day wears on, and in the evening one usually finds them at their best, and capable of some mental application. In dementia præcox, on the other hand, when despondency is present, it is constant, and shows neither daily nor hourly variations. The usual emotional attitude is that of increasing indifference and apathy.

Again, hypochondriacal ideas, while present in both neurasthenia and dementia præcox, are essentially different in each disease. In neurasthenia the hypochondriacal ideas are extensive, usually involving several parts or organs of the body; there is the feeling of pressure in the head, roaring of the ears, palpitation of the heart, coldness and numbness of the extremities, etc. In dementia præcox hypochondriacal ideas are far less extensive, and usually center about one or two organs, and are quite apt to involve the sexual organs. Furthermore, in neurasthenia, hypochondriasis tends to increase except as the disease abates, while in dementia præcox it tends to diminish as the disease progresses. Neurastheniacs are apt to complain of failing mental power, and express the fear that they are losing their minds in the absence of such symptoms, but in dementia præcox, evidences of deterioration really exist, which are not recognized by the patient. Finally, in dementia præcox, impulsive acts are often present, but are rarely encountered in neurasthenia.

*Hysteroid Cases.*—The following record represents cases of dementia præcox in which hysterical symptoms are prominent: The patient, a young woman of good family history, was always considered eccentric, unusually bashful, and somewhat seclusive. At the age of eighteen, while in service as a maid, she began to show greater timidity, and became more seclusive and reticent. Two months later she left her place of employment and returned home unannounced. Here she immediately went to bed and remained there, saying that she did not feel well, though she presented no objective signs of illness. She complained of headache, indigestion, and palpitation of the heart, but refused medical attendance. Whenever her mother insisted upon her leaving the bed, she regularly developed hysterical attacks with laughing, crying, screaming, and convulsive movements. In the course of four months she gradually improved, and upon the insistence of her mother, who found a place for her, re-entered service. She, however, worked indifferently and required constant prodding. Hysterical attacks were apt to recur at critical times when her assistance was most needed. Most of her time off duty was spent in her room, and she rarely went home to visit. Following this she frequently changed her places of employment, rarely staying longer than four weeks in any one place. These changes were usually made without warning, and always without excuse. On two occasions during the succeeding eight months she returned home for two weeks at a time, and suffered from what her physician called hysterical attacks. Finally she went home saying that she had had a vision, probably an hallucination, in which she claimed to have seen a black woman enter her room and touch her while asleep. By this time it was noticeable that she had lost interest in her personal appearance, and was paying little attention to her religious duties. Sometimes her mother would find her sitting on the floor laughing over her baby books. The tendency to indulge in unrestrained and meaningless laughter became more marked, and she would laugh not only at table, but also on the street. Two months later, about one year after the onset of the disease, the patient was first seen by me, and from this time the disease has presented the characteristic picture.

The hysterical manifestations early in this case would naturally obscure the diagnosis. In differentiating dementia præcox from hysteria, the following distinctions should be borne in mind: In hysteria there is always present what is termed the hysterical basis. This condition usually makes its appearance during puberty, and is irregularly manifested by various hysterical symptoms. Such a condition occasionally antedates dementia præcox, but is by no means essential. The emotional attitude is quite different in the two diseases. In hysteria the patients are entirely under the control of their feelings, and we find them vacillating from one mood to another, impelled by the most thrilling incidents. At one time they are extremely despondent, at another very angry, and again they are happy and cheerful, or sullen, but always craving sympathy. In dementia præcox the characteristic emotional state is one of emotional indifference and apathy, with an absence of reaction to the environment. Transient despondency, or moderate exaltation, may be encountered, but these states do not vary from hour to hour or day to day. In hysteria hypochondriacal symptoms are extensive and involve more than one organ, while in a dementia præcox they are limited. Hysterical paroxysms are characterized by both sensory and motor nervous symptoms. In dementia præcox the only paroxysms that ever occur are motor and of an epileptoid nature. In hysteria the mental processes of perception and comprehension are unimpaired. The patients are even keen in the recognition of their environment, especially any defects in it. In dementia præcox occasional hallucinations, such as occurred in this last case, are encountered very early in the disease. In hysteria genuine hallucinations and delusions are never present. What may seem to be hallucinations and delusions are found, upon close inquiry, to result from fabrication and a lively imagination. The store of ideas in hysteria rarely suffers any impoverishment, though voluntary conversation usually centers about the patient's ills, but in dementia præcox desultoriness, or scattered thought, in which there is a lack of continuity, often occurs early, while progressive impoverishment of ideas regularly accompanies the course of the disease. Finally, hysterical patients are extremely egotistical.

The necessity of an early recognition of dementia præcox becomes all the more apparent when one learns that the disease in the vast majority of cases has been in existence one or more years before the patient comes to the hospital, in which interval some have wandered from home and become lost to the family, others have developed alcoholic habits, or have acquired sexual diseases, conceived and given birth to children, or have committed criminal assaults, all of which might possibly have been prevented. The honor of the family, the protection of society, and the welfare of the patient demand more careful attention from the practitoner to this common mental disease.

---

**Conscientious Objectors in Great Britain.**—It is stated that 203,413 certificates of conscientious objection to vaccination of children were received last year by the vaccination officers of England and Wales.

**Traumatic Tetanus.**—Elsässer gives an exhaustive analysis of all the cases of traumatic tetanus observed in Kocher's clinic at Bern, and descants particularly on the results of the various modes of treatment employed. These embraced a number of variants of the usual combinations of narcotics, saline infusions, serum, and carbolic acid, and from the statistics obtained he has elaborated a definite plan to be followed as routine: (1) Energetic and prompt disinfection of the wound with tincture of iodine, carbolic acid, and in some cases the thermocautery. (2) The immediate injection of serum, either subcutaneous or intravenous, or in urgent cases intracerebral or subdural (lumbar puncture), in order to neutralize any free toxin circulating in the blood. (3) The free administration of opiates to anticipate convulsions. Most advantageous are chloral hydrate and morphine alternately. When necessary chloroform temporarily for severe seizures, accompanied by dyspnœa. (4) The systematic injection of carbolic acid in doses of fifteen minims of a 3-per-cent. solution every one or two hours, according to the severity of the case. (5) Subcutaneous infusions of salt solution for the purpose of contributing fluids in all cases, particularly when swallowing starts convulsions. (6) Feeding per rectum and, when indicated, by subcutaneous injections of oil (3-6 ounces) as recommended by Leube. (7) Isolation of the patient to avoid external stimuli. The greatest stress is laid on thorough disinfection of the wound at as early a date as possible, and for this purpose the two agents indicated, iodine and carbolic acid, are by far the most active. The tetanus serum, while of undoubted value labors, under the disadvantage of almost never being administered until the disease is well established, but the carbolic acid injections first advocated by Baccelli have a great and well demonstrated curative value. The mortality of the cases treated in the clinic according to the various older methods is 58.3 per cent., a remarkably favorable figure. —*Deutsche Zeitschrift für Chirurgie.*

**Subcutaneous Fat Absorption.**—H. Winternitz publishes a careful study of this question, and comes to conclusions differing widely from the generally accepted views. Since Leube's original experiments were described, the feasibility of employing subcutaneous injections of fats to supplement rectal feeding has been taken for granted, and both clinicians and experimenters have made use of the method. The mistake has been made, however, of considering all the fat found in the bodies of laboratory animals after injections of oils as representing an available fat supply for the organism to draw on. It is the author's view that whatever fat is to be of use to the organism must undergo oxidation, and that the efficacy of the method depends upon the amount of fat the body has actually been able to apply to its metabolic demands. By using iodized oils he has been able, as it were, to mark the fat he has administered, so that it is capable of subsequent identification on autopsy, while the iodine found in the urine gives an accurate index for the amount that has undergone oxidation. Experiments conducted along these lines, both in man and in animals, lead to the conclusion that fats do not afford a suitable medium for subcutaneous alimentation. While it is true, as Leube stated, that subcutaneously administered fats are absorbed and made use of by the organism, still the quantity so taken up is far too small to be of any use. After an injection of 500 gms. of oil under the most favorable conditions the amount absorbed during each of the first five days would not be more than 2-3 gms., while for the first eight days the figures would be still lower. That is to say, months would elapse before the 500 gms. would be absorbed, and a starving organism can take up only from 20-25 calories daily at the most from such injections.—*Zeitschrift für klinische Medicin.*

**A New Form of Sterilized Swabs for Surgical Operations.**—J. Jackson Clarke describes a swab which is triangular in form and consists of absorbent wool, everywhere covered with a double layer of soft gauze, which is so stitched that no rough edge and none of the cotton wool is exposed on the surface, thus reducing to a minimum the amount of cotton fiber that will be left behind in the wound when the swab is removed. At one angle is a pocket into which a finger, probe, or other instrument can be introduced; this greatly facilitates careful packing of a cavity or a large wound during the process of operation. For instance, in operating for appendicitis it is often difficult to pack in the ordinary square swabs without unduly pressing upon the surrounding coils of healthy intestine, while the insertion of the thin-pointed swab by means of the index-finger pushed into the pocket, can be done without difficulty, and the broader ends are then easily arranged so as to isolate completely the inflamed area. The ordinary process of hæmostasis is also facilitated by this form of swab held in the left hand with the tip of the index-finger in the pocket of the swab, the remainder of which is held in the hand. The general surface of the wound being freed from blood by the main part of the swab, the angle of the swab can be pressed by the index-finger on any particular vessel which is secured by forceps on raising the index-finger with greater ease than when a large surface with several bleeding points is suddenly exposed.—*Medical Press and Circular.*

**Of What Value Are Drugs in the Treatment of Children?**—Frederick Leavitt believes that, taking the world over, greater harm has been done children by the giving than the withholding of drugs. In such constitutional diseases as anæmia, rickets, scrofula, goiter, cretinism, acromegaly, Addison's disease and diabetes can we rely on drugs alone as exerting much influence in their cure? In infectious diseases how much real benefit is derived from the thousand-and-one indicated remedies? Is there a specific for meningitis, for pneumonia, or a common cold? Many of the diseases we try to cure are undoubtedly of benefit to the human race by their fatal consequences, as hydrocephalus, tuberculous peritonitis, etc. They are natural agencies which weed out the weaklings before they reach the age of reproduction. Aconite is of doubtful value, opium is a valuable drug, but needs the greatest care in its administration; digitalis is often useful, but should be used with the greatest circumspection; tonic restoratives are of less value than hygienic measures; chloroform, ether, and cocaine are necessary for anæsthesia, but not to be otherwise used; the coal-tar products are needless for the reduction of temperature, since water does it as well. Quinine is invaluable in malaria, mercury and potassium iodide work wonders in syphilitic affections; antitoxin in diphtheria is certainly a God-send, and the closing decade of the nineteenth century will be forever marked in the history of medicine because of its discovery.—*Pediatrics.*

**Hemorrhage of Typhoid Fever Treated by Calcium Chloride.**—Samuel E. Earp says that when the hemorrhage first appears an enema of one quart of water at 115° F. containing 60 grains of calcium chloride is to be used twice a day by means of a fountain syringe, held at an elevation of twenty inches. Thirty grains in solution is given by the mouth twice a day. This treatment is kept up from three to five days. At the beginning of the treatment some of the prepared liquid foods take the place of the milk diet, and the cold bath is abandoned. The diet should be simple and scanty for a few days. Powdered opium is to be used to retard peristalsis, and occasionally a low vitality will call for the nitrate of strychnia. On the fifth day the calcium chloride treatment is stopped, and five grains of salol or benzosol are given three times a day, and also an emulsion of turpentine, fifteen drops to the teaspoonful, every three hours. Several ten-grain doses of the subnitrate of bismuth may be used. In a few days the patient can again return cautiously to the milk diet if deemed advisable, and to the use of cold baths if there is a high temperature. Alcohol baths or cold packs may be used.—*The Medical and Surgical Monitor.*

## MODERN VIEWS ON GOUT.

THE *Practitioner* for July contains a symposium on gout. Dr. T. B. Futcher of Johns Hopkins University, in an article to which we referred recently, called attention to the frequency of gout in this country. Dr. Samuel West pointed out that the relation between gout and uric acid gravel and calculi is no simple one. Urine may contain excess of uric acid without depositing, and may deposit much when the contained amount is not large. Also the two conditions rarely occur in individuals or localities, and uric acid deposits in the kidneys occur in conditions other than gout. As shown by the statistics of Ord and Greenfield, Norman Moore, and Pye Smith, gout and chronic interstitial nephritis are closely, yet not necessarily, associated. But the association of lead poisoning with both diseases is also very intimate. Pointing out that granular kidney is a very common disease, West concludes that neither gout nor lead poisoning cause it, but that given the defective eliminating power inseparable from granular kidney, the liability to the development of gout or lead poisoning is greatly increased.

Dr. F. S. Toogood, writing on gout among the poor, says that only malt liquors cause the disease; spirit drinking does not. Dietetic errors do not enter into the etiology. Heredity is an uncertain factor, owing to the difficulty of separating rheumatism and gout in the histories. The age by preference is 40 to 50. Invariably the first joint attacked is the metatarsal-phalangeal of the great toe. Later lesions are much influenced by occupation strains, the joints most frequently involved being the great toe, the small joints of the feet, ankle, wrist, and fingers; rarely the shoulder, hip, and vertebræ. A very characteristic deformity is the fixation (by deposits) in hyperextension of the proximal-middle interphalangeal articulation with flexion at the middle-distal articulation. The only joint disease liable to be confounded with gout is osteoarthritis, acute attacks of which may present real difficulty, but here the inflammation is not quite so intense, or the skin so tense and shiny. Moreover, in gout the deformity is in the fibrous structures *around* the joint, whereas in osteoarthritis it is the joint itself and the bones immediately adjacent that are affected. Tophi aid, but they are often absent in gout.

Dr. Alexander Haig says uric acid produces two series of diseases, a local group (gout-rheumatism), and a circulation group (headache, epilepsy, mental disease, anæmia, Bright's disease, Raynaud's disease, etc.). If albuminoids are not taken in excess, the uric acid formed in the body does not harm, provided none be introduced. Haig discusses at length the subject of uric acid in the organism, and resolves the whole question into the physicochemical one of solubilty in the blood, and he explains all symptoms, even to detail, from this physicochemical standpoint. Remedies, too, are either solvents or precipitants of uric acid, and their effects follow naturally from this property. The two principles of treatment are to cut off the supply of uric acid and to eliminate that already present. In acute cases a solvent (sodium salicylate or salicylic acid) should be given in large doses. In chronic cases without fever or debility the same should be given, feeding up, however, with tonics and acid, and keeping the patient cool. With marked debility the patient should be well fed (without regard to ingestion of uric acid), and when he is better nourished salicylates should be given. Sir Dyce Duckworth, writing on a dietary, does not take seriously the various hyperfastidious distinctions so much in vogue, such as that white meats are "safe," while red ones are not, and he sees no sense in the notion that things grown underground are taboo. Iconoclastic as he is, when it comes to the subject of wines the distinctions drawn seem a trifle exiguous. Still his main contention is that the amount is to be curtailed markedly, and that a man's idea of moderate drinking is generally considerably too much. Any animal food is beneficial in moderation, though pickled and salted meats are best avoided. Indeed relief to the high liver comes not so much by yielding up some particular besetting sin, as by cutting down the total consumption. Dr. A. P. Luff applies to the acutely inflamed joint sodium bicarb. ʒ iv, lin. belladonnæ ʒ ii, tinct. opii ʒ iss, aquæ ad ʒ viii, mixed with an equal amount of hot water, on cotton under oil silk. For acute attacks colchicum is one of the most valuable drugs; 30–40 minims of the wine for the first dose, followed by 10–20 minims with 40–60 grains of potassium citrate. The first night 3 or 4 grains of blue pill should be given and the next morning Epsom salts. The first day or two bread and milk and tea made with milk instead of water should be given, and alcohol avoided if possible, as also beef tea and meat extracts at all times. Subacute and chronic cases require careful attention to diet, the securing of one stool a day, and small doses of colchicum with guaiac resin (5–10 grains) to stimulate hepatic metabolism and relieve portal congestion. The best alkali is potassium citrate. When the removal of deposits is in question sodium must be avoided, but when none is present sodium compounds benefit as hepatic and gastrointestinal stimulants. For reduction of chronic inflammatory thickenings iodide of potassium (5–10 grains t. i. d.) should be used, usefully combined with 5–10 minims of tinct. iodi. In subacute and chronic cases massage and galvanism (5–10 milliampères), and radiant heat and superheated air baths are very useful. Cataphoresis of potassium bicarbonate solution under 10–30 milliampères, benefits many chronic cases. The Turkish bath is most undesirable. Successful handling of the eczema requires the securing of regular defecation, careful dieting, and the entire avoidance of alcohol

and acid fruits. Locally, in dry eczema, liq. plumbi subacetatis ʒ i, liq. carbonis detergens ʒ i, aqua sambuci ad Oi, is most soothing; an opium preparation being substituted for the tar preparation in the moist eczema. Pruritus is best allayed by carbolic lotions. Insomnia and broken sleep are frequently benefited by a blue pill and a saline. For prophylaxis no drug equals guaiac resin (5 grains, increased to 10 or 12, after meals); quinic acid also seems of decided use. Much exercise (bicycling is an excellent form) is of great importance. The dietary should be simple and digestible, and should include at least one meat meal a day. Starches need only be curtailed when they produce indigestion. Alcohol as a rule is best avoided, but that depends on the patient. The best climate is one characterized by a fairly bracing air with a relatively low humidity.

---

## STANDARDIZATION OF DISINFECTANTS.

Mr. Samuel Rideal and Mr. Ainslie Walker read a paper on this subject before the recently held British Sanitary Congress, an abstract of which has been published in *Public Health* for August. The authors are of the opinion that in view of the steadily increasing demand for disinfectants due, in great measure, to the fact that the general public is acquiring a better knowledge of the true cause of zymotic disease, the efficiency of all disinfectants sold as such should have, if not a government guarantee, at least a maker's warranty which is capable of being checked.

At the present time there exists in Great Britain no official control over the sale of disinfectants, with the exceptions of those set forth in the Privy Council Orders of July 27, 1900, and June 5, 1902. The first of these permits the sale, without control, of liquids containing less than 3 per cent. of carbolic acid or its homologues as disinfectants, on the ground that such fluid is not a poison within the meaning of the Pharmacy Act of 1868; and "thus," say the authors, "has the direct effect, obviously, of placing a premium on inefficiency." In the subsequent order it is stated that liquid disinfectants containing scheduled poisons—which, for the present, are practically confined to carbolic acid and its homologues in solutions of more than 3 per cent., and corrosive sublimate—shall be sent out in bottles rendered distinguishable by touch from ordinary medicine bottles, with a label giving notice that the contents of the bottle are not to be taken internally. Formaldehyde and potassium mercuric iodide, which are both efficient disinfectants, can be advertised and sold as such by anyone without control.

The writers state that it has been suggested frequnetly that the example of Massachusetts of extending to such articles the provision of the Food and Drugs Act, should be followed. At any rate, the fact is patent that Parliamentary action is necessary to deal effectively with this particular problem.

In Great Britain, according to Messrs. Rideal and Walker, there is no thoroughly reliable test for disinfectants, which may account for this apparent apathy on the part of the authorities. "It is obvious," they go on to say, "that a bacterial rather than a chemical determination of efficiency is required. . . . Again, much depends upon the conditions, both chemical and physical, in which the disinfectant is employed. Thus it has been found that a disinfectant containing 10 per cent. of tricresol in emulsion is equivalent in bactericidal value to one containing 30 per cent. in solution when tested against a vigorous culture of bacillus typhosus."

While, however, it is agreed on all hands, that there is a great need of a bacteriological test, the methods employed by different bacteriologists result in glaring discrepancies. Consequently, in order to obtain results which would be comparable, a standard method for the examination of disinfectants must be employed. The authors submit that the following are some of the factors to be considered to attain this object: (1) Time; (2) age of culture; (3) choice of medium; (4) temperature of incubation; (5) temperature of medication; (6) variations in vital resistance of different species; (7) proportion of culture to disinfectant. The standard recommended is pure phenol, and the method advocated by the authors is as follows: To 5 c.c. of a particular dilution of the disinfectant in sterilized water add five drops of a twenty-four hours' blood-heat culture of the organism in broth; shake and take subcultures every two and a half minutes up to fifteen minutes. Incubate these subcultures for at least forty-eight hours at 37° C., allowing thirty seconds for each act of medication and the same time for making each subculture, four different dilutions of the disinfectant under examination, together with one standard control, may be tested against the came culture under conditions which make the results strictly comparable. If preferred, the field may be extended and divided into intervals of five minutes; but the authors contend that no table is complete which does not show a positive result in the first column and a negative result in the last. The strength or efficiency of the disinfectant is expressed in multiples of carbolic acid performing the same work; *i. e.* when a dilution of the disinfectant is obtained which does the same work as the standard carbolic acid dilution, the former is divided by the latter and so a ratio is obtained which is called the "carbolic acid coefficient."

With regard to the various factors enumerated above, their importance is clearly illustrated by numerous tables, but which can be only referred to very briefly. It is pointed out that to obtain regular and consistent results in the examination of disinfectants, time must be taken as the constant and strength as the variant. As to choice of medium, broth is recommended rather than agar, and with regard to reaction of the medium used for primary cultures, the authors have followed the lead of the American Public Health Association in 1898, by adopting a reaction of + 1.5 per cent. They have adopted 15° to 18° C. as the range of temperature most easy of attainment throughout the year. Respecting the proportion of culture to disinfectant. Messrs. Rideal and Walker say that "this is, perhaps, the most important factor of all, and yet it is one which is most frequently ignored. When a casual reader learns that a certain disinfectant is capable of destroying certain organisms within a specified period of time, he accepts the statement as a valuable contribution to our knowledge of the

article in question. Yet the absence of this factor entirely robs the statement of any value it might otherwise have. It is in cases such as these that we find the strongest argument in favor of a standard control."

The writers have shown that there is a great need of reliable bacteriological tests, a fact which has been more or less plain for some time. It would be well if the matter were fully discussed both in the United States and Great Britain, so that some decision might be come to regarding the establishment of a standard method for the examination of disinfectants.

## ALCOHOLISM AND HEREDITY.

At intervals during the past two years an animated discussion has been going on in *The Lancet*, with regard to heredity in connection with alcoholism. Many well known men have taken part in the dispute, and the conclusions arrived at by distinguished authorities have been freely quoted. Mr. G. Archdall Reid has been the most prominent disputant, indeed he may almost be termed the father of the new theory. Scientific and medical men for the most part have long held the view that certain acquired traits can be transmitted, and especially so with respect to alcoholism. That is to say, the son of a person addicted to alcohol will not on that account necessarily be an alcoholic himself, but he is likely to inherit a neurotic and unstable temperament, and will easily fall a victim to the drink habit. In fact, he will possess through the sins of his father a predisposition to travel the same road trodden by the latter.

Mr. Reid absolutely denies that this theory contains a grain of truth or has anything to recommend it, and he thrusts aside the assertions of noted biologists as founded upon misconceptions. In a paper read in the Section of Psychology, at the recent meeting of the British Medical Association, Dr. Reid set forth his opinions in a series of propositions. He calls his paper "Human Evolution with Especial Reference to Alcohol." The propositions are sixteen in number and far too long to quote at length here. The gist of his argument, however, is that races are resistant to any disease precisely in proportion to the length and severity of the ancestral sufferings from it; that disease does not extinguish a race, but actually strengthens it by the operation of natural selection; that parental temperance, like disease, does not affect offspring subsequently born. If offspring are affected, then races which have long used alcohol should be degenerate and tending toward extinction. On the other hand, if offspring are not affected, races that have longest used alcohol should, through the weeding out of the unfit, be the least inclined to excessive indulgence, the least susceptible to the charm of drunkenness, of all races. Mr. Reid claims that clear evidence is given that such is the case by the example of the Jews, Greeks, Italians, South Frenchmen, Spaniards, and Portuguese, who have longest had an abundant and continuous supply of alcohol, and who are the most temperate people on earth. North Europeans and others who have had a less plentiful supply are less temperate, while some savages and others who have had little or no experience of the poison are the most intemperate of all. In short, the contention is made that alcohol, like disease, is the cause of an evolution protective against itself. Drunkenness in the ancestry is the cause of temperance among the descendants.

Mr. Lawrence Irwell of Buffalo contributed to the *Medical News*, July 19, an article in which he treats of heredity and alcoholism. He says that alcoholic susceptibility is undeniably hereditary, but that the acquired taste for alcohol is not passed to the next generation, for if it were, the Jews, who have had alcohol for innumerable years, would have been almost wiped out by its use. If a few Jews were still left, they would be chronic drunkards, having inherited the desire for drink of many of their direct male progenitors added together. This is not so; indeed, the Jews, he says, are an extremely sober people, although their ancestors may centuries ago have been drunkards. Mr. Irwell does not believe in the transmission of an acquired drink habit, but yet believes in the inheritance of an alcoholic susceptibility. Whence then comes the alcoholic susceptibility? It must have either been acquired in the first instance, or the individual possessing it must have some peculiar abnormality of the brain or the nervous system generally, which drives him to seek relief in drugs or alcohol. The latter is doubtless Mr. Irwell's belief.

So far as the assertions made by Mr. Reid and Mr. Irwell are concerned, that the Jews and some other nations who have used alcohol from time immemorial are now the most temperate of races, there is no agreement on these points. Evidence that the Jews were at any time a drunken people is not forthcoming, while the Italians and South Frenchmen, mentioned by Mr. Reid as now being models of temperance, are declared by some apparently competent authorities to be quite the reverse. That Italians, Spaniards, Portuguese, and Greeks are races which have been for generations and are still on the down grade is a statement that needs little emphasis.

As Professor Cunningham said, "Mr. Reid cannot prove that the children of habitual drunkards are normally developed both mentally and physically. When drink is indulged in to excess through successive generations it results in insanity, paralysis, idiocy, or cerebral defect of some kind. "The theory that in a drinking nation the unfit are weeded out, and that among the survivors a considerable degree of immunity to alcohol is established, is plausible and probable. The craving for drink may not be directly transmitted, but the children of drunken parents or one drunken parent will in all likelihood inherit some physical or mental defect or both, which may of a certainty be put down to the drinking habits of their progenitors. To quote the opinions of Weismann and other biologists who have interested themselves in heredity and alcoholism would require pages. Suffice it to say that their views are divergent and that Galton was one of the first to propound the theory that acquired habits are not transmissible. Mr. Reid and his followers are earnest and able, and have done good by discussing and ventilating the matter, but until they bring more cogent and convincing reasoning to bear upon the subject, the mass of the medical profession will still hold to the belief that children born of drunken parents themselves inherit a certain degree of predisposition to drink.

**Death Rate of European Armies.**—The death rate in the German army is stated in *The Lancet* to be only 2.32 per 1,000; in France it is 4.58; in the United Kingdom 4.71; in Italy 4.87; and in Russia 5.32 per 1,000.

### Miners' Phthisis.

A disease to which those who work in coal mines are peculiarly liable is known as miners' phthisis. The symptoms which distinguish this malady during life are very similar to the symptoms of pulmonary tuberculosis, while the lungs are found, upon post-mortem examination, to be deeply pigmented and in a more or less solid condition.

Dr. Thomas Oliver of Newcastle-upon-Tyne, England, delivered an address on the subject at the recent meeting of the British Medical Association, which has been published in the *Medical Press* of August 19. It appears that miners' phthisis as a morbid entity has been known since 1703, when Ramazzini drew attention to it, and in 1860 Peacock proved microscopically and chemically the identity of the particles of dust found in the lungs with the dust of the atmosphere in which the patient had worked during life. The disease is one of occupation and caused by dust, also evidence goes to show that this form of phthisis bears a distinct relation to the kind of dust inhaled. Dr. Oliver says there are two ways by which the pathology of miners' phthisis can be studied: (1) Pathological inquiry in man, and (2) physiological experimentation in animals.

The point, however, of Dr. Oliver's address was as to whether pneumokoniosis is a tuberculous disease. The speaker contended that it was not, and that when tubercle was present in miners' phthisis, it was an accidental and, therefore, a secondary infection. On the other hand, Dr. Tripier of Lyons is convinced that tubercle is not a coincidence nor a secondary infection, but the principal cause of pneumokoniosis. It is a fact worthy of notice that, however foul the air of underground workings may be when the ventilation is fairly good, and especially if the dust is prevented from impregnating the air, lung disease is rare among the workers in such localities.

Dr. Oliver summarized his conclusions thus: (1) Miners' phthisis is not caused by the inhalation of any of the gases present in the mine. (2) In pneumokoniosis there may be not only excess of fibrous tissue, but even cavities and tubercle. (3) The disease, is, however, non-tuberculous. (4) Accepting this view of the pathology of the disease, there is hope that by improving ventilation and by allaying the dust with water, miners' phthisis may be still further diminished.

---

### Increase of Insanity in Great Britain.

The annual report of the Lunacy Commissioners of the United Kingdom shows that insanity has increased considerably in England, Scotland, and Wales. Reference was made editorially to the increase in Scotland in the Medical Record, June 6, and in the same number the connection between drink and insanity was commented upon. According to a cable dispatch to the *Sun*, August 2, the increase in the number of insane in the United Kingdom during the year ended December 31, 1902, has been phenomenal. No less than 22,581 are reported to have become insane in 1902. The cases of lunacy are tabulated as carefully as is possible in the Lunacy Commissioner's report. Drink is one of the predominating causes, it being responsible for 23 per cent. of male and 9.6 per cent. of female cases. To heredity is ascribed 24.6 per cent. of the cases of insanity amongst women, and 18.8 per cent. of those amongst men. The figures of the report do not bear out the general belief that to the strain and stress of modern life is due much of the increase in lunacy. The Commissioners argue from the data collected by them that the increase of lunacy has its origin rather in physical than in mental causes. It is a curious and significant fact that insanity is increasing more rapidly in the country than in the cities. Dr. E. W. White, the recently elected president of the Medical Psychologico-Association, states that the most discouraging feature with regard to the increase of lunacy is the fact that in the past thirty years there has been no material advance in the rate of recovery, despite the numerous new and rational principles of treatment. Dr. White advocates as remedial measures, State regulation of marriages so that those tainted with lunacy should not be permitted to propagate their species, and Government control of the manufacture and sale of spirituous liquors. There can be now no doubt that insanity is on the increase in Great Britain, as it probably is to a greater or less extent in all nations of the civilized world. It is a pity that reliable statistics regarding insanity cannot be obtained from all parts of the United States. They would be of much scientific value for purposes of comparison.

---

### The Toxicity of Methyl Alcohol in Extracts and Medicine.

Dr. R. H. Main read before the Pike County Medical Society in Pittsburgh, on April 23, a paper bearing this title. He relates the case of a man—a patient of his own—who through drinking large quantities of lemon extract died with all the typical symptoms of methyl alcohol poisoning.

The author then made a series of investigations of various culinary extracts, and was surprised to find that many of them were made from methyl alcohol in contravention of the pure food law of Illinois. Dr. Main quotes largely from the writings of well-known medical and scientific men to prove the toxicity of methyl alcohol, which has the peculiar property of rendering its victims blind.

*The Johns Hopkins Hospital Bulletin*, August and September, gives the results of a series of twenty-eight experiments made by Dr. Reid Hunt of Baltimore with methyl alcohol and ethyl alcohol. From these experiments he deduces the following: The symptoms of intoxication by wood alcohol are produced more slowly than by grain alcohol and the period of intoxication is more prolonged. The effects of a single dose of methyl alcohol are long continued, and it is an especially dangerous substance to give for any length of time. . . . The highly important discovery has been made that methyl alcohol differs markedly from ethyl alcohol, in that it is but partially oxidized in the body, and that its administration leads to the formation within the body of the highly poisonous formic acid. After its administration to an animal or a man a considerable amount of formic acid can always be found in the urine. Formic acid is excreted very slowly. This is probably the cause of blindness which so frequently follows methyl alcohol poisoning in man. Highly differentiated nerve structures are especially likely to suffer when exposed to the action of a poison for a long time. Dr. Hunt concludes that, "however pure methyl alcohol may be, it is totally unfit as a substitute for grain alcohol in any preparation which is to be taken internally, and especially in a preparation which is to be taken for any length of time."

Dr. Main asserts that methyl alcohol is used extensively in the manufacture of our culinary and medicinal extracts, spirits, essences, etc., and he further states that he has abundant evidence in support of his assertion.

In the discussion that followed the reading of Dr. Main's paper, Dr. Gehrmann proposed the following

resolution: "In view of the fact that we recognize the poisonous effects of methyl alcohol, when used internally and externally, be it resolved by Section 3, of the State Medical Society, that the State Food and Drug Commissions be urged to take action to prevent its use in all pharmaceutical and culinary preparations as a substitute for alcohol, and that where it is used in the arts special precaution be taken to protect workmen from its effect." This resolution was carried.

### The Possibility of Ridding a District of Mosquitos.

In connection with the prevention of malaria, it is agreed on all hands that if mosquitos could be extirpated that the disease would soon be extinct. Of course, no one is sanguine enough to anticipate the wholesale destruction of the malaria-bearing mosquito, but there are many who are of the opinion that rigorous measures energetically carried out will in certain districts reach this end in a very satisfactory manner. Others believe that hope in the consummation of any such plan is a Utopian idea, and that our defence against the pestilential insects must lie in denying them ingress to our dwellings, and protecting our bodies.

Drs. Stephens and Christophers, who have been studying the subject in the malaria-infested regions of West Africa, have recently made their report to the British Royal Society. The London *Times*, commenting editorially on the same, remarks that on the question of the prevention of malaria in native communities Drs. Stephens and Christophers do not speak hopefully, and even express their belief that, with the means at the disposal of the sanitary bodies of West Africa, no appreciable diminution of the disease is at present to be brought about. The destruction of anopheles larvæ was at first regarded hopefully; but this hopefulness has diminished as the magnitude of the undertaking has been realized, and as the first attempts have shown the difficulty of conducting such an operation upon a sufficiently large scale. If drainage could be efficiently carried out over a particular area it would, they think, be successful in diminishing native malaria, but the conditions surrounding each case must determine to what extent such a measure could be applied.

This is one side of the picture, but Dr. Ronald Ross, in a letter to the *Times*, presents the other side of the picture. He shows that it has been practically proved that native malaria can be driven out by destroying the offending mosquitos. Dr. Ross enclosed a communication he had received from Major Penton, principal medical officer of the Soudan, which records the successful results which have already followed the anti-malarial campaign—conducted upon the lines suggested by Ross—commenced less than a year ago by the Suez Canal Company at Ismailia. "The results," says Major Penton, "have been remarkably successful. The town is practically free from mosquitos, which only a short time ago were very abundant. Mosquito nets can almost be dispensed with. . . . The operations you recommended are in full swing. Two marshy swamps to the northeast of the town have been filled with sand, others on the south have been filled, while still others are being dealt with. . . . Coincident with the destruction of mosquitos and other larvæ, malarial fever at Ismailia this year shows a most striking improvement. Statistics show that up to the present it is the healthiest year on record."

This evidence, while by no means demonstrating that it is possible to destroy mosquitos everywhere and thus make an end to native malaria, is nevertheless the most favorable testimony to the efficacy of thorough preventive measures that has as yet been afforded. If malaria cannot be entirely extinguished, it can be so scotched that it will no longer be the dread menace it has been in former times to Europeans living in tropical countries.

### Susceptibility of Criminals to Atmospheric Changes.

Weather undoubtedly exerts a certain amount of influence upon the state of a person's mind. In fine, breezy, sunshiny weather even a dyspeptic misanthrope cannot but feel an exaltation of spirits; while on the other hand rain, fog, and a cold, irritating wind will render a Micawber depressed. It is generally agreed that weather affects individuals in a normal condition of health, but how it influences criminals until recently has not been made a subject for inquiry. Dr. W. Norwood East, Deputy Medical Officer H. M. Convict Prison, Portland, gives in *The Lancet*, July 25, the result of some investigations into the question undertaken by him among the convicts of Portland Prison. Dr. East's inquiry with the object of ascertaining if atmospheric changes influenced the criminal resulted in showing that this class is, on the whole, insusceptible to such influences. However, the conclusions reached seem worthy of being recorded briefly, as sustaining the assertion that the criminal is deficient in reactivity to external influences. For the purpose of Dr. East's investigations a period of three years was taken, during which time he noted the direction of the wind, the outlook, the temperature in the shade, and the barometric height, taken daily at 8 A.M. at the prison, and to estimate the possible effects on the criminal the number of breaches of prison discipline was compared. The investigations tended to show that the criminal did not appear to be affected to an extent worthy of mention by the outlook. Wind appeared to have some slight effect, but so small as to be hardly a matter for consideration. Barometric variations appeared to have no influence, but rapid variations of temperature were thought to be slightly antagonistic to healthy functional action in criminals. "In onclusion," says Dr. East, "it may be considered that, with a possible exception in the case of variations of temperature, the criminal is unaffected by atmospheric changes.

**Hydrotherapy in Pediatrics.**—M. Barts says that he has never derived such satisfaction in treating febrile diseases in children, especially scarlet fever and cholera infantum, as since adopting the use of the tub bath in all severe cases. As to temperature the same results can be obtained with a bath at 90° for a child that would require one at 70° for an adult. In all ordinary cases 10 to 12 minutes duration is sufficient, in some cases 5 to 8. The soothing effect of the cool bath on the child is a strong argument in its favor. The benefits of the bath are greatly increased by the free application of cold water to the head while the child is in the tub. Hot baths are indicated not in acute febrile conditions, but in the chronic stage characterized by exhaustion. Sometimes a thorough sponging or a wet pack, cold or hot, will give as good results as a tub bath. Water is also beneficial when used internally. In cholera infantum and other gastrointestinal disorders, milk diet should be stopped, and the stomach irrigated and the large intestine washed out with normal salt solution. The irrigation of the bowels should be continued two or three times daily in all severe cases of enterocolitis. The author cites ten cases in support of his views.—*The Cleveland Medical Journal.*

# News of the Week.

**The Prize Essay of the American Medical Association.**—This association offers annually a gold medal, value of $100, for the best essay on any subject relating to medicine or surgery. The recipient of this prize will be given the option of the gold medal, or a bronze replica of the medal, and the balance of the appropriation (about $90) in money; or the entire amount ($100) in money. The association annually sets apart the sum of $500 for original research, and this prize is offered to stimulate the production of a superior practical paper based upon either experimental studies or clinical investigation or both. The committee will give preference to papers having the greatest brevity consistent with thorough consideration of the subject, and recommends that the paper shall not exceed 5,000 words. The committee, while not restricting the choice of subjects, recommends as an important subject for consideration "The Therapeutic Value of the Digestive Ferments." Competing essays must be typewritten, and bear no mark revealing their authorship; but instead of the name of the author there must appear on each essay a motto, and accompanying each essay a sealed envelope containing the name of the author and bearing on its outer surface the motto of identification. No envelope will be opened by the committee until a decision has been reached as to the most deserving essay. The other essays will be returned to their respective authors. The committee reserves the right to reject all essays if none is found worthy of the association medal. Competing essays must be in the hands of the chairman of the committee not later than April 1, 1904. The committee consists of Lewis S. McMurtry, Louisville, Ky., chairman, Burnside Foster, St. Paul, Minn., and M. H. Fussell, Philadelphia, Pa.

**The Health of Cuba.**—The newspaper reports of a mysterious disease near Santiago de Cuba and the assertion of a physician formerly resident in Cuba that the disease was yellow fever, have directed attention anew to health conditions in the island. It is of interest therefore to learn from a recent report of United States Minister Squiers that the sanitary measures introduced by Colonel Gorgas are continued in Havana and that the island as a whole is now more healthful than at any time in its history. Minister Squiers says: "In the District of Havana the death rate decreased in June to 400, against 448 in the preceding thirty days and against 540 in June of last year, and is the lowest figure for the month of June ever recorded in Havana, as far back as reliable statistics can be obtained. The whole island is free from smallpox and yellow fever. In many of the provinces the death rate has been abnormally low for the time of year, owing to the improved methods o fsanitation."

**Yellow Fever in Mexico.**—In a report recently received by Dr. George R. Taber, Health Commissioner of Texas, from Linares, Mex., it is stated that the municipal authorities are taking no steps toward controlling the epidemic, and the yellow-fever cases are not quarantined. The city jail is reeking in filth, and the sick prisoners are forced to lie on the damp earth floor of the cells. The average daily number of deaths from the disease at this time is about eight. It is stated that yellow fever has spread during the past few days to Montemorelos and Teran, which are situated close to Monterey, and it now exists in every town and village between Monterey and Tampico on the Gulf Division of the Mexican Central Railroad, as well as in Monterey itself. The Texas Health Department has purchased fumigating plants which it will install at Laredo and Eagle Pass. Dr. I. P. Seisson of Rockdale, Texas, has been sent to Monterey by the State Health Department to make a further investigation of the situation at that place.

**An Expedition for the Study of Trypanosomiasis.**—The Liverpool School of Tropical Medicine has despatched a trypanosoma expedition to the Congo Free State. The objects of the expedition are to report to the school, and through it to the Congo Free State Government, on the sanitary conditions of Boma, Leopoldville, and other important centers to be visited, and to make recommendations for the improvement of existing sanitary conditions; and, further, to continue the investigation of trypanosomiasis, human and animal, commenced in the Gambia by Dr. Dutton, 1901, and continued in the Gambia and Senegal by Drs. Dutton and Todd. The special points to be studied are the occurrence and distribution of trypanosoma in the Congo, the carriers of the parasite, and the relation of trypanosoma to sleeping sickness. The commission is composed of Drs. J. E. Dutton, J. L. Todd, and C. Christy.

**The Cause of Pope Leo's Death.**—According to a despatch in *The Sun* of September 13, Drs. Lapponi and Mazzoni, the physicians of the late Pope Leo, have published a defence against the attacks made upon them by Dr. Cardarelli of Naples, who recently published a pamphlet in which he accused them of making an incorrect diagnosis of the Pope's disease, and declared that the Holy Father died of cancer instead of pleurisy. The defence shows that singular and apparently causeless intrigues were going on at the Vatican during the Pope's illness. Both physicians say that they detected the true nature of the Pope's illness, but Cardinal Rampolla, the Papal Secretary of State, objected to having it made public. When the symptoms became clearer they insisted upon being allowed to protect their reputations against easily foreseen criticism, but Cardinal Rampolla was immovable. He even refused to have it announced that a third operation of thoracentesis had been performed, although Drs. Lapponi and Mazzoni did perform such an operation. The physicians, therefore, wrote in the presence of a witness a full history of the case, giving the real nature of the disease. Copies of the statement were given to Cardinal Rampolla and the major domo of the Vatican.

**Typhoid Fever in Philadelphia.**—It is pointed out that while a considerable number of the cases of typhoid fever have occurred in residents of districts supplied with filtered water, many of the victims have been employees in the mills and have drunk canal water, through which no doubt their infection was acquired. Others, it is believed, have been infected at summer resorts and elsewhere.

**"It Is to Laugh."**—One of the provisions of the substitute Panama Canal treaty which the Colombian Congress offers in place of the Hay-Herran treaty, just rejected by that body, is that the sanitary commission of the Isthmus, both during and after the digging of the canal is "to be exclusively Colombian." There must be an undertaker lobby at work in Bogotá.

**Damages to Physicians for Railway Injuries.**—Dr. Hubbard W. Mitchell of this city recently brought suit in the Supreme Court at Jersey City against the Jersey City, Hoboken, and Paterson Street Railway Company, claiming $50,000 damages. Dr. Mitchell was riding in one of the company's cars which was derailed and he was thrown to the floor, his head striking the seat on the opposite side.

CASE XVII.—Quartan. Total count, 6,000.

| Differential count: | WOOD'S STAIN. |
|---|---|
| Small mononuclears | 6.5 per cent. |
| Large mononuclears | 24.1 " |
| Polymorphonuclear neutrophilics | 69.3 " |
| Eosinophiles | .1 " |
| | 100.0 per cent. |

From a consideration of the differential leucocyte counts present in these cases of malaria, it is at once seen that in many instances of this disease the differential count so closely simulates that present in many cases of typhoid during the first week that a separation is impossible. Certain of these cases of malaria (eight out of seventeen) show a marked relative increase in the polymorphonuclear neutrophilics, and hence could be easily differentiated from typhoid. By looking over them it will be seen that, as a rule, they show a much less relative number of eosinophiles than do the typhoid cases. These cases of malaria were all febrile cases, and the smears were made at the time they appeared for diagnosis. In them the relative number of eosinophiles was almost always below 1.5 per cent. and usually below 1 per cent., while the reverse holds true for the typhoid counts. Just how important a point this is in separating the differential counts of these diseases, I do not know. This point can only be determined by increased observations.

*Conclusions.*—1. Many cases of typhoid fever, contrary to general supposition, show the characteristic differential leucocyte count within the first week of the disease.

2. The definite value of the differential leucocyte count in the early diagnosis of typhoid fever is as yet problematical; but it seems certain that when used in addition to the total leucocyte count, more information may be obtained than by employing the total count alone.

In conclusion, it gives me pleasure to acknowledge my indebtedness to Prof. T. Mitchell Prudden and Dr. Francis C. Wood for valuable suggestions during this work.

227 PARK PLACE.

**The Relation of the Islands of Langerhans to Diabetes Mellitus.**—Albert Ernest Finney concludes that (1) Diabetes may occur in the absence of any demonstrable lesion in the islands of Langerhans, and the glycosuria in such cases may be of nervous origin, or may correspond to the type described as "alimentary glycosuria." (2) Diabetes may occur accompanied by lesions of the islands, which, however, are not of sufficient extent to be in accordance with the results of Mehring's and Minkowski's experiments on extirpation of the pancreas. In such cases it is possible that the islands which present no anatomical lesion may have become functionally inactive. (3) Diminution in number of the islands in diabetes may occur in various proportions, even to total disappearance, and where such diminution is slight, its only importance is the inert, or retrogressive, condition of the islands which it implies. (4) Lesions of the islands may occur in the absence of diabetes, being in such cases of slight extent, and never of primary nature. (5) Diabetes may, lastly, be associated with lesions of the islands apparently primary, and even confined to the islands themselves. These consist in hyaine transformation, and specific necrobiosis.—*The Medical Chronicle.*

## A CASE OF LEUCOSARCOMA OF THE CHOROID.*

BY THOMAS R. POOLEY, M.D.
NEW YORK.

THIS case is reported because of the comparative rarity of non-pigmented sarcoma of the choroid, as well as on account of some points of interest in its clinical history and anatomical findings.

The patient, a man aged thirty-five years, came under my care on December 12, 1902, in my clinical practice. He was possessed of very limited intelligence and could give but little account of his symptoms. About three weeks before I saw him he thought he had gotten something in his left eye, and as his eye continued irritable, and he found that he could not see with it, he applied for treatment. He did not complain of severe pain in the eye at any time, and is sure that before the time referred to he saw very well with it.

When I examined him, this eye showed the typical features of absolute glaucoma: Circumcorneal injection of a venous character, hazy cornea, wide immovable pupil, shallow anterior chamber, anæsthesia of the cornea, T 3; entire absence of reflex with ophthalmoscope, and no perception of light. I made the diagnosis of absolute glaucoma, probably caused by tumor of the choroid, and thought enucleation should be done forthwith. Yielding, however, to the opinion of several of my colleagues, that it might be primary acute glaucoma, or due to a hemorrhage, I consented first to try iridectomy, which operation I did the same day. The operation, with the patient under ether, was successfully accomplished and resulted in a large coloboma; the anterior chamber, however, immediately filled with blood.

On December 14 there was some diminution in the tension of the eye, but hardly any absorption of the blood. By December 17, however, the blood in the anterior chamber was diminished, when, on the 18th, a fresh hemorrhage took place, nearly filling the anterior chamber and accompanied by pain and increase of tension. There was again an attempt by nature to absorb the blood, but fresh hemorrhage always took place, and, on January 3, 1903, I got the patient to consent to enucleation of the eye, which was done without any mishap, and, because of my belief that there was a tumor, I divided the optic nerve as far back in the orbit as I could. The healing was uneventful and the patient was discharged a few days later.

After being hardened in 10 per cent. formalin for a week, the eye was examined by Dr. Edward B. Coburn, pathologist of the New Amsterdam Eye and Ear Hospital, whose report is as follows:

From a photograph by Dr. Edward B. Coburn; dotted line (x) showing connection of the parts of the tumor by a narrow band.

"*Macroscopically.*—Shallow anterior chamber. Iris atrophic, with coloboma (from iridectomy) upward and adherent to the lens capsule. Lens appears swollen as though forced into the space

*Read before the American Ophthalmological Society at Washington.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

THE WEATHER AND PUBLIC HEALTH—ARE WE DEGENERATING? ROYAL COMMISSION AND OTHER REPORTS ON NATIONAL PHYSIQUE—THE WAR ON MOSQUITOS IN EGYPT—DEATH CERTIFICATION—THE LATE DR. CORFIELD.

LONDON, August 28, 1903.

MANY persons are returning prematurely from their holidays, driven home by stress of weather. Even those who content themselves with week-ends have been bitterly disappointed this year. Some of us manage to reverse this plan and come to town once a week to clear up important matters in hospital or private practice. But these, too, have found the arrangement almost as bad as those who went off to some favorite place for a month or six weeks' change. Those, too, who went to the continent are hurrying back in disgust. This August, the holiday month for most doctors, is the worst for about fifty years, according to the records, and about as bad as last year, according to my recollection. I need not describe it—the cable and the newspapers will have done that for you, and from the same sources I gather you have no stones to throw at our climate. Of course the few who postpone their outing for the shooting season are hoping that the floods and gales and other conditions will have given place to something more enjoyable by the end of the month. I have once or twice spoken of the possible "Indian summer" approaching, but without giving or feeling much encouragement. And now a French professor is pretending to forecast the British weather for all September, and he gives as dismal a prediction as if he were an enemy determined to destroy the *entente cordiale*. I comfort myself with the conviction that anyone assuming in the present state of our knowledge to forecast the weather for a month is only a quack. Let him keep his evil prognostications to himself.

In spite of all the adverse conditions the public health has not suffered. Last week's mortality returns are favorable. The deaths were 542 below the average of the corresponding week. There were no deaths from typhoid fever or smallpox. But the deaths from diarrhœa, which had been 83, 95, and 139 in the preceding three weeks, rose to 184. But even this figure is 128 below the corrected average.

Are we degenerating? is a question that is frequently put in the course of conversation, with more or less earnestness. The educationists—as they call themselves—are quite sure we are, and have managed to sound the alarm in Parliament. Having crammed the children with all sorts of useless knowledge and interested the easier classes in their need of better houses, better clothing, and better food, the cry is now raised that degeneration is proceeding so rapidly that the next generation will be very inferior, and after that—. Sir John Gorst's opinion is being quoted as if he were infallible, since he told the House of Commons that if its members "could realize the true condition of children who go to primary schools they would be appalled at the degeneracy which is coming upon the people," and went on to declare that unless something be done to arrest it "this country will degenerate in physique." Those who accept this observation and conclusion say that the legislature must be moved to avert the approaching catastrophe at all cost, which would appear to mean that the children must be fed at the cost of the ratepayers. But it hardly seems feasible to convert all primary schools into boarding houses and pauperize the majority of the community. There seems a want of perspective in the views of these extreme alarmists. If they would make an investigation into the condition of the peasantry a generation or two ago they would find it much more "appalling" than at present, and probably become convinced that diet is not the only factor of the physique of a nation. The cry of alarm has been reinforced by reference to the inferior diet of the schools of the upper and middle classes. In these also there has certainly been a great advance. I have had the opportunity of comparing dietaries of the present day with those of forty and fifty years ago, and can testify to the improvement. Certainly parents who take the trouble to inquire can find plenty of schools in which the diet is abundant. So if this is the only factor of strength, England may yet remain a great nation.

The report of the Royal Commission on Physical Training in Scotland has now been published, and may be noticed in connection with the subject. The statements made by the medical examiners for the commission are certainly not reassuring, and are supported by the report of the Inspector-General of Recruiting. The medical examiners in question examined 1,200 children in board schools in Aberdeen and Edinburgh, 600 of all ages and both sexes between the ages of six and fifteen in each city, noting the height, weight, nutrition, mental condition, disease, deformity, and other personal points, as well as the state of clothing, housing, food, and cleanliness. You will not be surprised to learn that the examiners found a large number of these children the subjects of unrecognized phthisis, cardiac and other diseases, while lesser ailments abounded among them. The importance of the facts is obvious, and it is most desirable that they should be known. But whether they justify the alarmists is another question. Any doctor who took a stroll through the poorer quarters of great cities might observe a number of ill-fed children in a condition to call for medical care, but whose parents had not felt any anxiety about them. Can we suppose that this is a state new to the present generation and sure to make the next a mass of degenerates? The report of the anthropometric committee scarcely supports the pessimism of the commissioners, who seem to have begun their work with a conviction that rapid deterioration has set in. This committee showed that so far as measurements of stature and weight go the population is not deteriorating. The report of the Inspector of Reformatory and Industrial Schools also shows that "the slum population of the country has not deteriorated during the past twenty years, but has, if anything, improved." I put these statements against those of the Royal Commission, and take hope for the country. It is not necessary to dispute some of the conclusions of the commission. For instance, we are told that "there exists in Scotland an undeniable degeneration of individuals of the classes where food and environment are defective." I am afraid that in New York and, indeed, other cities the same statement might be made as to "individuals whose food and environment are defective." As to the remedy, the commission recommend "a well-regulated system of physical training," surely a very questionable prescription for insufficiently fed children.

Ismailia is a low lying town on the Suez Canal, and is, moreover, surrounded by swamps. Malaria was, from its foundation, endemic there, and considered to be due to its position. It is now an object lesson of the truth of the mosquito theory. The authorities have for nearly a year been carrying out preventive measures under skilled advice. The marshy pools have been filled up, the water drained off, and the small channels connected with the canal cleared. The effect is that the present year is the healthiest that Ismailia has known. From January 1 to June 30 there were only three cases of malarial fever in the hospital as against fifty-two for the same period of 1902. Throughout the town there were last year from January 1 to May 30 no less than 569 cases. This year for the same time the number was seventy-two, and the medical men think a considerable proportion of these were relapses. Thus Ismailia may look forward to the complete suppression of the plague of malaria. Major Ronald Ross has communicated these results to the *Times*, and he is confident that other tropical towns have only to act as thoroughly as Ismailia has done to attain the same result. Major Penton, Principal Medical Officer of the Soudan, says that when the men began the work they were greatly worried with the mosquitos. Now they hardly see any, and mosquito nets are becoming almost unnecessary, and on a recent visit he slept without one and was not bitten. It has been suggested that we should discard the misnomer malaria for a more correct appellation.

Reform of our methods of death registration has often been urged by the profession for the protection of the public. It seems time to demand it in our own interests. In illustration of this I may mention a case at the late Glamorgan assizes when the judge blamed a medical man for having given a certificate of death which had been used in order to defraud an insurance company. A child was brought to the doctor in such a state from measles and chest complications that he was not at all surprised to be told next day that it was dead. In accordance with the common custom he gave the certificate, as he had no reason to suspect deception. But the child was not dead, and the judge thought more caution should have been exercised, and told the doctor he could have held his hand and left the case to the coronor. But so long as the law requires a certificate but does not require inspection of the body it is not to be expected that the present custom will cease, for the doctor who made a rule to refer to the coroner or to inspect the corpse of every patient would run great risk of having no patients left.

Dr. W. H. Corfield, Professor of Public Health at University College, and Medical Officer of Health for St. George's, Hanover Square, died on Wednesday at Marstrand, in Sweden, to which he had gone in search of health. He has been an invalid for the last three years, though some months ago he rallied to a promising extent. His career has practically been devoted to sanitary work and teaching, and he wrote several books on the subject, all of them well received. He was sanitary adviser to the office of works. He took a first class in natural science at Oxford, where he graduated. He was in the sixtieth year of his age.

## OUR BERLIN LETTER.

(From Our Special Correspondent.)

HUMAN AND BOVINE TUBERCULOSIS—SURGERY OF THE LUNGS—MALARIA—BLACKWATER FEVER—PROPHYLAXIS OF MALARIA—A NEW REMEDY AGAINST SEASICKNESS—OBITUARY—HEIDELBERG'S CENTENARY.

BERLIN, July 31, 1903.

Two years have elapsed since Prof. Robert Koch expressed at the London St. James's Hall his opinion that human and bovine tuberculosis were not identical; experiments have been made since and there is yet discussion in certain quarters whether Koch's opinion is right or whether the old opinion that there is a unity between human and bovine tuberculosis is correct. The question was again discussed at a recent meeting of the Berlin Medical Society. Professor Lassar demonstrated several cases of dermatitis verrucosa in persons who had been dealing with cows affected with tuberculosis. He expressed his opinion that this disease was caused through the tuberculosis of the cow. Lassar examined during the last ten years 108,000 persons affected with skin diseases, of whom 34 only were suffering from vaccinal tuberculosis—"notorische Impftuberculose." He also examined 365 workers in the slaughter-house, whom he found affected with tuberculosis verrucosa cutis. From these facts Lassar deducts the conclusion that his experiments once more prove the unity of human and bovine tuberculosis.

Dr. Kossel of the German Imperial Board of Health gave the results of experiments which he had made together with Dr. Weber. He made injections from 39 different cultures of bacillus tuberculosis, 23 of which were taken from adults, 16 from infants; 19 cows gave no symptoms whatever; 9 cows showed, four months later, a slight inflammation of the glands, which remained local; 4 only gave the well-known symptoms of a general tuberculosis. Yet these cultures were not taken from the most virulent kind of tuberculosis, but from infantile tuberculosis of the intestine.

Dr. Kossel concludes that the opinion that only bovine tubercle bacilli can cause bovine tuberculosis is justified, and that notwithstanding two children died of bovine tuberculosis, the general fear which exists of an infection from bovine tuberculosis is by no means justified. In the discussion Dr. Max Wolff said he had been able to cause human tuberculosis in cows. Dr. von Hansemann and Professor Orth supported this view. Dr. Schuetz spoke against it. The question, Dr. Lassar admitted, is yet an open one. Of course sanitary measures in feeding the cows cannot be given up, and the existing law preventing tuberculous meat to be sold ought still to be enforced. Further experiments have still to be made.

Dr. Karewski read a paper at the Verein für innere Medizin on the surgical treatment of abscesses of the lung. An abscess is caused by pneumonia, by foreign bodies which have penetrated into the lungs, or by embolism of a septic nature. Spontaneous perforation and evacuation do sometimes happen, yet it always remains unknown whether the abscess has totally disappeared. The necessity of an operation arises from the danger of general sepsis. Abscesses in the inferior lobe give the best results; those in the upper lobe are less amenable to treatment.

Dr. Plehn read a paper on "Malaria and Blackwater Fever." The latter is always due to malaria. The nearer the equator, the more frequent is blackwater fever. In the Roman Campagna it is rare, in Camerun it is frequent. It is caused through the destruction of the erythrocytes. Quinine is not the cause of blackwater fever, as an outbreak may take place in cases in which no quinine has been used. In 168 cases of blackwater fever, twenty-four of the patients had received no quinine. It occurs only after a certain sojourn in the tropics for not less than three months, but there are few colonists who in their third year do not suffer from it. The more the erythrocytes have been affected through the parasites or through quinine, the sooner blackwater fever occurs, and it is wrong to give quinine when the attack is taking place. Patients generally recover soon and no signs of the disease remain.

New remedies against sea-sickness come out every year. They are all good in the inventor's hand, but after a time no one hears more of them. The newest theory is that of Dr. Cornelius, medical officer of the German army. Dr Cornelius, who had seen good results with his theory of special "points douloureux" in nervous and hysteric cases, tried his theory also on sea-sickness. On a steamer bound to New York he experimented on several passengers. His results were that several "points douloureux" exist close to the sternum between the ribs in persons suffering from sea-sickness. Massage of these points caused the symptoms to disappear. But whenever massage was omitted the symptoms reappeared. Dr. Cornelius constructed, therefore, an apparatus having the form of a belt with several knobs which pressed on these painful points. One was applied in the region of the occipital nerve, the second one round the thorax, the third one round the abdomen. The symptoms disappeared and patients who made use of this apparatus suffered no more.

The Central Committee for First Aid to the Injured—a Berlin institute created to extend first aid in cases of accident—will send a delegate to the St. Louis World's Fair and take part at the Exhibition.

On July 31 the physiologist Professor Immanuel Munk died, aged fifty-two. He is known through several important studies on the resorption of albuminoids and through his standard work on the physiology of man and the other mammals.

Dr. Ewald has returned from America and has published a report of his journey and his experiences made in the United States. He speaks in praise of the American hospitals and especially of the operating rooms, and the asepsis which is strictly enforced. Of special interest to him were the American gymnasiums and the numerous athletic clubs which he thinks of high importance for the public's health.

The old center of medicine, the University of Heidelberg, is celebrating its centenary. Professor Czerny is at present rector of the university.

---

## EXPERIMENTS WITH THE McGRAW ELASTIC LIGATURE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: With reference to Dr. Kakel's report on the elastic ligature, I will say that when I first experimented on dogs I operated on a large number with unvarying success in producing a good anastomosis. Of late I have seen two specimens of this work on canines, in which there were partial failures. I attribute my success, in the first instance, to the quality of my rubber cord. It had been made for operations on piles, was two millimeters in diameter, very elastic, and absolutely unbreakable.

After ten years in my office it was found to retain all of its elasticity and tenacity. I have never been able since to find quite so good an article.

Notwithstanding the fact that my own experiments were made on dogs, I regard it unfortunate that that animal should be always chosen for this kind of experimental work. The dog's intestine is so much thicker, tougher, and more contractile than the human that it is no criterion by which we may judge of the effects of operations on the thin and comparatively weak human bowel.

I do not think that there is a case on record in which a post-mortem examination four days after the application of the elastic ligature in the human subject has failed to reveal a perfect anastomosis. If any surgeon has had such an experience I should like to know it. I have, once on the living subject and three times post mortem, had occasion to examine intestines which had been subjected to the ligature operation, after that lapse of time, and in every instance the result was all that could be desired. Yesterday I examined the stomach and jejunum of a physician upon whom I had made a gastroenterostomy, sixty-six hours before his death. It was a case in which the patient had refused all operative relief until a continuous black vomit indicated the disintegration of the mucous membrane. I had refused to operate, but changed my mind when he showed some signs of improvement.

In this case, one of cicatricial stenosis of the pylorus with an enormous dilatation of the stomach, I used a small ligature, very strong and elastic. On examining the place of operation, I found that the ligature had made a minute opening at one end. The mucous membrane and peritoneal coats of both stomach and jejunum had been cut through and only exceedingly thin sheets of the middle coats still held the ligature. In another six hours the anastomosis would have been completed. In this case there was no sepsis, and the patient died of exhaustion consequent on starvation.

It was interesting to note the condition of the tissues around the ligature. All the surfaces included in the line of Lembert sutures were adherent. Outside of that line there was no adhesion nor appearance of congestion. The adhesions were strong enough to protect, but not strong enough to prevent that expansion of the bowels which can occur only after the ligature has cut through. After the ligature has done its work it leaves a small slit connecting both bowels; on the edges of this slit, which, though apparently short, has a length equal to that originally included in the ligatures, the muscles pull until the intestine unfolds to its original length.

As regards the character of the ligature, it should be hard, round, elastic, and strong. I do not know that any advantage would accrue from increasing its size. If, however, the surgeon chooses to do so, he could get the

greater size by doubling the small ligature. I have known a surgeon to use successfully a small elastic catheter, but I should not recommend it, as it has neither the desired hardness nor the elasticity.

THEO. A. MCGRAW, M.D.

DETROIT, September 4, 1903.

## REPORTS OF PLAGUE IN PERU AND CHILE.

(From Our Special Correspondent.)

AREQUIPA, PERU, July 28, 1903.

SINCE last month Peru and Chile have been in a state of excitement and uncertainty as to the existence of bubonic plague in their territories. Even now it is difficult to get hold of facts—some among the medical profession maintaining that there is plague, others denying its presence. The alarm began in Callao, the port of Lima. It was said that a vessel had arrived from India bringing wheat and the plague. This had not the appearance of truth, seeing that wheat is never brought from india to this country. Rice is occasionally brought, though it has to pay considerable duty on entering, as Peru is a rice-producing country; so we are all made to pay for the benefit of a few native rice-producers. Later on the story was that grain had been brought from Mazatlan by steamer. Then a certain mill in which had occurred two deaths among the employees, and several deaths among the rats, was looked upon as the holder of this grain, now turned into flour. At once there was a general cry that the mill (I understand, without the inhabitants) should be burned. It is said that some of the flour was taken out and the gamins amused themselves throwing it at people, calling out "Take the plague." Strange to say, one now hears no more of plague in Callao, but there come telegrams from Iquique, Chile, saying that it exists there and that there are daily several deaths. The Chilean government has declared Iquique infected. Can it be that mistakes have been made both in Peru and Chile? Perhaps so. If, as Dr. Kinyoun said at the meeting of the American Medical Association, May 7, "Plague might resemble anthrax, tonsillitis, mumps, diphtheria, erysipelas, pneumonia, acute pleurisy, malignant pericarditis, endocarditis, typhoid, typhus, relapsing and malarial fevers, acute dysentery, miliary tubercle, septicæmia, pyæmia, and syphilis," then it is no wonder that there are doubts about its diagnosis in a population which has no experience of it; and I suppose it takes a somewhat skilled observer to make the microscopical diagnosis with certainty.

The alarm has caused the Board of Health and the municipality here to make some spasmodic efforts as to hygiene, chiefly taking the form of excellent (paper) resolutions and recommendations. Unfortunately the word "quarantine" has come to the front and soothed us to sleep again. That is one of the worst effects of quarantine, viz., that it paralyzes reform as to sanitary measures. What, say the people, is the use of bothering if the disease cannot gain an entry into the country? That quarantine can be made effective in Peru is impossible. Peru has a seaboard of about 1,000 miles, the greater part uninhabited. Landward its confines, with other countries, are much more than a thousand miles, and even more sparsely inhabited than the coast. To think that, if plague exists in any of the neighboring countries, some of their panic-stricken inhabitants cannot and will not effect an entrance into Peru is absurd.

**Appendicitis without Symptoms.**—Richard Jones reports the case of a girl of thirteen who walked into his office complaining of a pain and vomiting after eating a large green apple the previous evening. Her face was expressive of pain, she was slightly bent forward and inclined to the right; her right leg and hip were in advance of the left as she crossed the room. An enema of opium, asefœtida, turpentine, and warm oil was ordered, and gave some relief, but the following day the symptoms plainly pointed to general peritonitis. Operation was performed, but the patient died the day after. The appendix had thickened and hard walls; the interior being covered with ulceration throughout its whole extent, and showing concretions of a dark slate color covered with mucopus. There was a gangrenous patch with a perforation in its center. The appendix must have been undergoing these changes since a previous slight attack the year before, without a single symptom of any kind until the moment when the peritoneum was attacked.—*The Australasian Medical Gazette.*

## Progress of Medical Science.

*The Boston Medical and Surgical Journal, Sept.* 10, 1903.

**The Relations Existing between Respiratory and Intrapelvic Diseases.**—Daniel H. Craig says that his attention was first directed to the relations existing between respiratory and intrapelvic lesions by the fact that patients with pelvic lesions, especially those with ovarian prolapse, were invariably made worse and their favorable progress under treatment arrested by the intercurrence of any cough-accompanied lesion. Attention was paid to the question of antecedent respiratory lesions in all cases in which ovarian prolapse existed. Positive histories were obtained too often to allow of its being considered merely coincidental. The writer thinks that at least a part of the so-called congenital ovarian prolapse cases may be due to the congestion and pressure effects of respiratory diseases—for example, whooping-cough—during childhood, no symptoms manifesting themselves until after the maturation of the organs. The following prophylactic suggestions are offered: The congestion of menstruation acting in conjunction with that of cough is always harmful, and even the nulliparous should be guarded against it. As corsets lessen decidedly the normal abdominal resiliency and go far toward destroying the so-called retentive power of the abdominal mechanism, they would better be proscribed during any severe and long persisting cough-accompanied lesion, especially during the catamenia. By assuming the prone position for a few minutes after a violent coughing spell, disengorgement of the pelvic vessels is favored and gravity assists the ovarian supports. Pelvic respiratory massage may be very beneficial in ovarian or pelvic involvement. This consists in having the patient assume the genupectoral or knee-elbow position and aspirate the pelvic vessels by slow force-expiration about fourteen times a minute.

**Theory and Application of Mechanical Vibration in the Treatment of Disease.**—Maurice F. Pilgrim states that, in its broadest sense vibration is the most abounding, the commonest force in the universe with which we are familiar. For example, hearing and sight are scientifically recognized as the result of the rapid vibrations in the universal ether. In the vibratory stroke mechanically produced we may get (1) stimulation, (2) sedation, and (3) inhibition, depending upon its length, force, and the duration of its application. Whether the stroke should be long or short depends upon the depth of the location of the nerve to which the vibrating stimulus is sought to be applied. The deeper the nerve or nerve center, the greater the intensity of the physical abnormality and the more remote its location from the spinal center, the longer, proportionately, should be the stroke. The treatment should be localized. Treatment should usually be applied between the transverse processes of the spinal vertebræ which are immediately over the posterior division of the spinal nerves that control directly or reflexly the nutrition of the diseased viscera or area. By this treatment, nutritive processes are improved as well as secretion and excretion; elimination is also increased. Muscular and general systemic metabolism is enhanced with greater oxidation and the production of more animal heat. The respiratory function is also improved. Its sedative effects are marked in cases of general nervous irritability, excitability, fatigue, and very markedly in insomnia. The inhibitory power is shown in the prompt relief of pain and in the dispersion of congestions or engorgements. The writer knows of no other single physical agent that will accomplish so many good results, as the one under present discussion.

*Journal of the American Medical Association, Sept.* 12, 1903.

**Should the Tuberculous Patient Know the Truth Regarding His Condition?**—C. P. Ambler believes that it is the duty of the physician to explain to the patient the dangers to himself and to others and to appeal to him to make an effort to protect his friends. Unless we tell him the truth it will be impossible to secure from him the cooperation necessary to effect a cure. We should discuss with him, not merely the tuberculous features of his case, but go fully into the details of the whole question of hygienic living.

**Cramp of the Ciliary Muscle Due to Eyestrain.**—J. W. Wright notes two causes of ciliary cramp. (1) An emmetropic eye may have cramp of its ciliary muscle. Too much near-work leads to it. Impairment of the general health will augment it, but the cramp may exist in an emmetropic eye when there is good health from too much near-work. (2) The ametropia conduces to it, especially hyperopia and astigmatism, whether hyperopic or myopic. In mixed astigmatism there is great predisposition to the cramp with a tendency to headaches and eye pains. This

may be attributed to the unequal contraction of the sphincter fibers in order to obtain a clear retinal image. The cramp is not constant. One of its first symptoms aside from headache and pain in the eye itself is that vision for distance varies. Distant vision may be good, but the cramp returns on the least exertion at near work. For treatment the author advises instillation each night of one drop of a combination of equal portions of one per cent. homatropine solution and 2 per cent. cocaine solution. He also gives the following internally: ℞. Morphia sulph. gr. i; liquor potassi arsenitis tinct. gelsemium (green root), āā 3i; Elixir simp. q. s. ad. ℥iv. M. Sig.: One tablespoonful every six hours until headache ceases.

**The Influence of Consanguinity on the Organs of Special Sense.**—Several cases are described by L. W Dean, the eye being the organ specially considered. Out of 181 institution patients who were blind, he found that excluding from the list those children who were blind because of blennorrhea neonatorum, sympathetic ophthalmia, trachoma, etc., and considering only those who suffered because of congenital conditions 14 per cent. were the result of consanguineous marriage of the first degree. Two factors he says may enter into the production of many of these conditions: (1) The eye is really an outgrowth from the brain, and is consequently subjected to the same conditions as the central nervous system during its development. (2) The eye is changing, and an organ that is adapting itself to new conditions is more liable to malformation than one with a constant condition. The socket is becoming less deep and the superciliary ridges less marked. His figures suggest one or two interesting conclusion: (1) The relation of the inheritability of a condition to its production by consanguineous marriages. I would judge from these cases that the greater the inheritability of a condition the more liable is it to be the result of consanguineous marriages. Theoretically this would also be the case. Retinitis pigmentosa is a disease of great inheritability. (2) Note is made of the fact that where there is an arrest in development as in the cases of microphthalmos coloboma of the iris, congenital cataract, and anophthalmos, the eyes are in an opposite state to those of eyeless fishes and worms where they have been lost by disuse. (3) There is a resistance of the eye tissues after operation. While there is an arrest of development, nutrition is apparently normal.

*Medical News, September 12, 1903.*

**Infantile Scorbutus.**—Thomas Morgan Rotch reports two interesting cases which illustrate the care that should be taken to differentiate between an advanced bone lesion of scorbutus and the bone lesions which arise in osteomyelitis and osteosarcoma. The first patient was a boy of ten months who had been fed on cereal milk and had seemed perfectly well till the present illness. The right lower leg became tender and swelling developed. Acute osteomyelitis was diagnosed. The skin was pale. There was a marked rosary and enlarged epiphyses of both wrists and ankles. There were two lower middle incisors. The gums were slightly reddened about the base of the teeth, but there was no distinct stomatitis ulcerosa. The prominent feature was the swelling of the right leg from the knee to the ankle, especially marked above the outer malleolus. Within about three weeks three operations were performed. By this time the left leg was in a condition similar to that of the right when first seen. There was little or no benefit from the operations, and the child grew steadily worse till seen by the writer. Orange juice was ordered, and the little patient's condition has improved steadily up to the present time.

**A Proposed Apparatus for the Treatment of Empyema.**—Francis M. C. Usher describes this apparatus: It consists of a metallic or glass box (1) of about 300 c.c. capacity, with top and bottom screw-threaded perforations, a perforated nipple screw-top (2), a perforated screw body flange (3), and a section of pure bandage rubber of suitable size (4). The application of the instrument to the body is effected by fitting the hole in the center of the rubber, the screw of the body flange, and then screwing the flange to the drainage box, making an air-tight junction between the rubber and the instrument. The under surface of the rubber is then cleaned and roughened with emery cloth, and a coat of rubber cement is applied and allowed to dry, the corresponding surface of the body over which the rubber is to be applied is also cleaned, coated with cement, and allowed to dry. On application of the rubber to the body it will be found to adhere very tightly, making an air-tight junction between the instrument and the body. If now the top is screwed on and connected with an exhaust pump by means of a rubber tube fitted over the perforated nipple, the air partly exhausted and the rubber tube tied, the instrument can be worn with comfort and will maintain a partial vacuum for an indefinite period. The apparatus would, of course, be useless if the pleural abscess communicated with a bronchus. Its use would best be suited to early cases, and by its preventing the collapse of the lung the usual hesitancy about making an opening into the pleural cavity would be overcome.

*New York Medical Journal, September 12, 1903.*

**Surgical Shock, with Special Reference to the Solar Plexus as a Factor.**—The clinical picture of the familiar surgical shock is described by J. J. Dandmant, who gives in full the anatomical relations of the solar plexus. Direct injuries in the region of the latter produce a paralyzing effect, which is communicated to the auxillary plexuses with the usual result of vasomotor paralysis of the abdominal vessels, rapid and irregular heart action, and finally a cardiac dilatation which may be fatal. In addition there is the added effect of paralysis of the inhibitory nerves of the heart. The same result follows, though more slowly and less violently, when organs are involved at some distance from the plexus; so also the plexus may become benumbed by the absorption of septic material. The author refers to the case of President McKinley, disputing the truth of the official statement that gangrene was the cause of death. The special feature to which he would call attention is the absence from the official bulletins of all mention of symptoms suggesting a grave condition, except the pulse rate, which was rapid throughout. A heart which beat for six or seven days at a rate of from 120 to 140 would certainly become exhausted and fail to respond (as did the President's heart) to stimulation.

**The Value of Confirmatory Cultures in Diphtheria.**—From an extensive experience in the New York City Health Department, J. P. Billings, Jr., offers the following conclusions: (1) A certain small percentage of cases of true diphtheria fail to show diphtheria bacilli on first culture, this failure being due in many instances to a conjoined infection with the septic micrococci. With the exception of these cases, the statement that a case is probably not diphtheria can be made on one negative culture up to the tenth day of the disease. (2) Valid reasons for requesting a confirmatory culture in negative cases are: (*a*) Cases showing no growth whatever on the culture medium; (*b*) complete contamination and liquefaction of the culture medium, in cases which are clinically diphtheria; (*c*) cases showing the presence of suspicious or diphtheria-like bacilli; and (*d*) croup cases in infants or children, when the membrane is limited to the larynx, and the duration of the disease is less than five days. (3) Dryness of culture medium, scanty growth on culture medium, and recent use of antiseptics with satisfactory growth of other organisms than diphtheria bacilli, do not alone furnish sufficient grounds on which to request a confirmatory culture. He further states that in view of this experience it has been decided to report as "non-diphtheritic" every negative culture in cases lasting ten days or less, except that a confirmatory culture will be asked for. (*a*) When there is no growth on the culture medium; (*b*) when the culture medium is completely contaminated and liquified, and when the clinical diagnosis is diphtheria; (*c*) when suspicious or diphtheria-like bacilli are present; (*d*) when the membrane is limited to the larynx, the duration of the disease is five days or less, and the clinical diagnosis is croup or laryngeal diphtheria.

*American Medicine, September 12, 1903.*

**Condition of the Blood in Rheumatoid Arthritis and Osteoarthritis.**—William G. Erving gives an interesting review of work done on this subject in forty selected cases. In both sets of cases the figures show a red blood-corpuscle count ranging slightly above normal, while the hæmoglobin percentage is close to the 100 mark. This is surprising when it is noted that the condition occurs not only in robust, healthy men with acute osteoarthritic symptoms of but a few weeks' standing, but also in the pale, sallow, listless, and poorly nourished sufferers from a more or less general rheumatoid arthritic involvement. The slight leucocytosis noted in most of the cases seems to bear no relation to the severity of the symptoms or to the duration of the disease. The differential leucocyte counts, though showing some slight variation from normal, particularly in the decrease in the per cent. of polymorphonuclear and increase in the mononuclear elements, as seen in the rheumatoid arthritic group, is certainly not striking. The condition of the blood is not what would be expected in disease of such a general wasting nature. No abnormal elements, such as microcytes, macrocytes, nucleated red corpuscles, nor other signs of hæmic degeneration, were found, and, to all appearances, in the acute stages of the disease, the formed elements of the blood are practically unaffected. Further observation can alone determine the reason of this apparent disagreement between clinical appearances and microscopical findings.

**Splanchnoptosis Caused by Omental Adhesions.**—Daniel H. Craig, in speaking of splanchnoptosis, states as a well-known fact that elocutionists, singers, and actresses, who in learning correct articulation first learn correct breathing with a certain amount of use of the abdominal muscles. These individuals are much less prone to unsightly abdominal enlargement than are women not so trained. The inference from the foregoing is that if direct downward pushing by improper corsets and other clothing, and muscular atony with its attendant downward tendency of the viscera could be avoided, splanchnoptosis could be avoided instead of being on trial for cure. The prophylactic measures are then the proper adjustment of clothing and the strengthening of the general muscular system with very especial attention to the musculature of the abdominal parietes. The writer then reports three cases in which operation was performed. These three patients presented the common factors of pelvic peritonitis and marked constipation, although the peritonitis was far from a prominent factor in the history of the last case. The writer thinks this a strong warning against undertaking the operative correction of gastroptosis in cases in which any history of pelvic peritonitis can be obtained without making the first step of the operation a thorough exploration of the condition of the great omentum. The omentum contains large vessels and is very easily torn, and very decided upward traction is exerted on tightening the sutures in the gastrohepatic omentum. Even though these sutures are tightened easily, the stomach and colon coming easily up into position, there is no guarantee unless the omentum is explored that the operation will be successful or even safe when the patient assumes the upright position. The writer urges that care be exercised in early operations lest these excellent operations, which are entirely rational, and in properly selected cases most successful, be unjustly condemned because improperly used in improperly selected cases.

*Münchener medicinische Wochenschrift, August 25. 1903.*

**Sepsis with a Complicating Miliary Tuberculosis.**—Robert Schlüter reports a case which is of interest in that a miliary tuberculosis was ingrafted upon a general sepsis instead of the reverse, which is usually the case. The early symptoms were all septic and responded in certain measure to appropriate treatment. After several weeks pulmonary physical signs appeared which gave rise to the suspicion that the lung lesions were tuberculous in nature. At this time a slight reaction followed the injection of Koch's tuberculin. At autopsy tuberculous lesions were found in the lungs, spleen, liver, larynx, and meninges. It is of course, possible that the case may have been one of tuberculosis or mixed infection from its inception, but the early symptomatology and results of treatment render this improbable.

**Treatment of Hæmatocele.**—P. Zweifel advocates the immediate operation with the removal of all the blood in the peritoneal cavity in all cases except when the hæmatocele is incapsulated. While the immediate operation in acute cases is recommended by the majority of authors, many advise against the complete removal of the blood and confine the operation to measures directed toward controlling the hemorrhage, maintaining that the blood in the peritoneal cavity will be readily absorbed. In the majority of cases acute hæmatocele is due to a ruptured tubal pregnancy, and when we consider the abundant changes for inflection under such conditions it certainly seems unsafe to leave the mass within the peritoneal cavity. Experience shows that the operation with complete removal of blood gives excellent results, for of fourteen cases operated on by the author since 1890 all recovered. Incapsulated hæmatoceles should only be operated upon when acute symptoms arise.

*Berliner klinische Wochenschrift, August 24, 1903.*

**Action of Dead Tubercle Bacilli and the Toxins of Tubercle Bacilli.**—Victor Klingmüller claims that the toxins of tubercle bacilli and the dead organisms when introduced into tissue produce pathological lesions which cannot be distinguished from those produced by the living bacilli. This is proven by the microscopical examination and inoculation of the tuberculins obtained from various sources. The old tuberculin regularly contains tubercle bacilli which are dead, while the new tuberculin contains none, yet the lesions produced in the reaction following their inoculation are identical and entirely similar to those produced by the living bacilli.

**The Omentum as an Organ of Protection.**—E. de Renzi and G. Boeri by a series of experiments upon dogs have shown that the omentum is a protective organ of great value to the animal economy. If the circulation of the spleen or kidney is cut off so that the organ becomes necrotic, infection does not occur, as the mass is incapsulated by the omentum and undergoes gradual absorption. If, however, previous to such an operation the omentum has been removed, the necrotic tissue of the ligatured organ rapidly produces death by general infection. A similar incapsulation with protection occurs when foreign bodies are placed within the peritoneal cavity. If we add to this protective property the ability of the omentum to supply an abundant collateral circulation in cases of ligature of the portal system as takes place in Talma's operation for cirrhosis of the liver we see that this portion of the peritoneum must not be disregarded in its usefulness to the body, and that it may be utilized in the future for therapeutical measures which are as yet unheard of.

*Deutsche medicinische Wochenschrift, August 20, 1903.*

**A Case of Thrush General Infection.**—O. Heubner reports a case of general infection with the thrush fungus in a child one and one-quarter years of age. The clinical picture closely resembled that of diphtheria, although the throat appearances were, perhaps, a trifle more scarlatinal in character, and there was a well-developed pustular eruption over the chest and back. Death took place on the fifth day under the picture of advanced sepsis. At autopsy the oidium albicans was isolated from the tonsils, kidneys, and lungs. In the necrotic portions of the tissue the mycelia were most abundant, but abundant spores were found in the underlying tissue. The fungus was cultivated in pure culture, which upon inoculation into rabbits gave positive results.

**Biochemistry of Pregnancy.**—Erich Opitz gives the results of his initial experiments looking toward the production of an anti-eclamptic serum. By inoculating animals with the placental tissue devoid so far as possible of blood he has evolved a serum which causes the precipitation of certain substances in the serum of eclamptic patients, but is without any such action when mixed with the serum of healthy pregnant or non-pregnant women. It is therefore more than probable that there has been thus produced a syncytiolysin or antitoxin against the syncytio-toxin which arises in the blood of pregnant women from the breaking down of placental tissue, and which when in excess and not neutralized by the maternal organism gives rise to the clinical picture which we know as eclampsia. Much work will have to be completed before such an antitoxin serum can be made available for therapeutical purposes, but of such ultimate use there can be but little doubt, as the biological basis of the work thus far completed is to be considered as entirely sound.

*French and Italian Journals.*

**Apomorphine in the Treatment of Alcoholism.**—Antonio Vaccari has for ten years or more administered hypodermics of apomorphine to quiet violent attacks of drunkenness. About 1 centigram given in one-per-cent solution induces vomiting in from five to ten minutes and the patient quiets down and falls asleep. No untoward effects have been observed as a result of the treatment.—*Annali di Medicina Navale*, June, 1903.

**Hepatic Insufficiency in Malaria.**—Jean Carrive describes a case in which the stages of disease were the following: (1) Malaria characterized by the presence of hemotozoa in the blood. (2) Hepatic insufficiency almost to the point of non-function. The symptoms of this condition are hyponitrogenization, alimentary glycosuria, intermittent elimination of methylene blue, hypocholia. Decided diminution of hepatic dulness. Delirium. (3) Diabetes with marked polyuria and polydipsia.—*Archives Générales de Médecine*, August 11, 1903.

**Complete Recovery After Grave Purulent Pleurisy.**—A. Besson reports a case from which he deduces the following conclusions: In purulent pleurisy, with streptococci, or with associated microbes, and in putrid purulent pleurisy, pleurotomy should be performed. Thoracentesis is of value only in pleurisy with pneumococci; in children it will usually bring about a complete cure, whereas in adults, absolute recovery occurs in a few cases only. If two or three operations do not bring about the desired result, pleurotomy must be at once resorted to.—*Journal des Sciences Médicales de Lille*, August 15, 1903.

**Treatment of Abdominal Contusions.**—M. M. states that when a patient has received a contusion of the abdomen, indications for treatment should be sought at once, even before the condition of shock has passed off. Contraction of the abdominal walls, or signs of effusion or gas call for immediate operation. Should no physical sign be found, the patient must be questioned as to the accident. If the blow was a violent one striking the umbilical region perpendicularly to its surface, the patient's muscles being in a relaxed condition at the time, it will be almost certain that one or more of the abdominal viscera have been injured. Intervention in such a case should not be delayed.—*La Tribune Médicale*, August 15, 1903.

**The Action of Quinine on the Virus of Rabies.**—Adriano Valenti instituted a number of researches on rabbits and in the laboratory, and concludes from the results obtained that the virus of rabies *in vitro* completely loses its virulence when in contact with the alkaloids of cinchona, especially quinine. As quinine is known to have an elective action on the protozoa, this would seem to sustain the theory of Negri that the pathogenic microorganism of rabies is a protozoon. It is impossible as yet to say whether this action of quinine has any clinical value; the author intends to make further researches in this line.—*Gazetta Medica Lombarda*, July 12, 1903.

**Rapid Cure of Burns Due to Incandescent Wires.**—S. Szczypiorski says that burns of this nature involve skin muscles, tendons, nerves, vessels, and even bone. The section is linear and never bleeds. If we make topical applications we have to wait for slow healing by granulation with the formation of an irregular cicatrix and sometimes impaired function of muscles, tendons, and nerves. The author prefers to disinfect the wound and excise all the cauterized tissue. If the bone is involved the mortified parts are gouged out. A raw wound is obtained which can be at once sutured, thus shortening the period of recovery, restoring the functions of the tissues and producing a simple cicatrix. Three cases are reported.—*Gazette des Hôpitaux*, August 18, 1903.

**Non-articular Tuberculous Rheumatism.**—M. Revillet quotes Poncet in defining this variety of affection as one in which the rheumatic attacks are not confined to the joints, but are expended as well on the organs, muscles, nerves, etc. It is as much a clinical entity as articular rheumatism, and is useful in giving the clue to the nature of certain symptoms which appear either before or after the onset of pulmonary tuberculosis. It indicates the form of treatment to be followed. Sodium salicylate and its derivatives are contraindicated. They are of no value in this pseudo-rheumatism, and usually impair the gastric functions. A milk diet is weakening, and, indeed, what these patients need is an excess of alimentation. Phenacetin seems to calm the pains, and exposure of the affected parts to the sun's rays has given excellent results.—*Journal des Praticiens*, August 15, 1903.

**Death from Chorea.**—M. Vicq says that death may occur in uncomplicated or in complicated chorea. In the first case it may be due to exhaustion, the ending of grave, intense generalized chorea; it may also occur abruptly in choreas of medium severity. In the second class of cases it may be due to some *cardiac* complication—endocarditis, pericarditis, asystole; to *nervous* trouble—acute mania, apoplexy, coma; *digestion* complication, acute dilatation of the stomach; *respiratory*—pneumonia, pleurisy, asphyxia; or it may be occasioned by some *infection* developed from cutaneous excoriations—abscess and phlegmon of the limbs, gangrene, septicmia, or from the general choreic conditions, as tuberculosis, scarlatina, diphtheria, typhoid fever. It is evident that even in cases of apparently benign chorea, the prognosis must be somewhat guarded, as it is impossible to predict whether some grave disorder may not occur as a complication, or whether the disease itself may not become aggravated and lead to a fatal issue.—*Gazette des Hôpitaux*, August 13, 1903.

**Experimental Intrahepatic Infections.**—Giuseppe Javi coli draws the following conclusions from his experimental researches: The injection of a sterile liquid into the hepatic parenchyma does not cause any appreciable symptoms of intolerance. Virulent cultures of malignant pustule, diphtheria, and of the pneumococcus are more likely to be lethal when injected directly into the liver than when injected subcutaneously. The diphtheria bacilli when inoculated into the liver remain localized in this organ without spreading into other tissues. Bacteria do increase in virulence by being injected into the liver. Infection by the liver is always more grave than by the subcutaneous tissues. The macroscopical and microscopical changes in the organs, especially in the liver, are more marked in infections determined through the liver than through the subcutaneous tissues. The microchemical reactions of glycogen has always been positive in animals which have died as a result of intrahepatic injections of bacteria.—*Giornale della Associasione Napoletana*, March and April, 1903.

**Nephritis of the New-born and of Nursing Infants.**—Enrico Mensi from his study of the subject comes to the following conclusions: That bronchopneumonia is a frequent cause of nephritis in nursing infants. The anatomicopathological lesions involve the epithelium, especially of the cortical substance, rarely affecting the vascular apparatus or the glomeruli. The lesions are usually tubular, whether microorganisms are found in the kidneys or not. The clinical symptoms, especially those connected with the vascular and nervous apparatus, are not constantly in direct relation to the renal function. This fact must be due to urinary intoxication and to individual susceptibility. Hereditary influence is evident in some cases. There is no proof that the liver plays any part in the causation of uræmic symptoms. The prognosis of nephritis in nursing infants depends upon that of the causative disease.—*Rivista de Clinica Pediatrica*, August, 1903.

**The Therapeutic Value of the Cold Sitz-bath.**—M. Caulet and M. Macrez state that it is impossible to say at exactly what temperature a bath should be given, for what to one patient seems a tepid bath, to another seems cold. Sensation is the only guide. A *cold* bath is characterized by an initial chilly feeling, rapid contraction of the capillaries, and maintenance of the central temperature, which is *not* lowered. A cold sitz-bath is preferable to a cold douche, because after the first chill and quick breathing there is no gasping, no suffocation, no rapid heart action with filiform pulse. Reaction is gently and gradually accomplished, causing a sensation of warmth and comfort. With the douche, subsequent exercise must be taken and persevered in, that reaction may be complete, but with the sitz-bath this is not necessary. It is therefore to be preferred to the douche in the case of enfeebled, sensitive patients, and whenever there is occasion for great care in regard to the organic or functional condition of the cardiovascular apparatus.—*Bulletin Général de Thérapeutique*, August 15, 1903.

*American Journal of the Medical Sciences, August*, 1903.

**Rheumatism vs. Muscular and Joint Pains.**—James J. Walsh says that many cases with the diagnosis of rheumatism are examples of muscular and joint pains due to quite other causes. Among the most prominent causes are: flat-foot, occupation brachyalgias and shoulder pains of various kinds due to the excessive or faulty use of muscles. In neurotic conditions pain is a very relative affair. In highly excited neurotic states even a little discomfort may seem almost unbearable pain. A case of tabes came under the notice of the writer in which the lightning pains took the form of sciatica and were treated as sciatica rheumatism. A very interesting set of cases of pseudo-rheumatism were noted as occurring in connection with scoliosis. In one case joint symptoms occurred in an arthritic neurosis of the knee consequent upon the pinching of a loose cartilage in the joint. Hysterical joints are sometimes mistaken for cases of obstinate subacute rheumatism. In pulmonary tuberculosis pains at the bases of the lungs are sometimes spoken of as rheumatic. Wherever there is pain for which no simple explanation is forthcoming the word rheumatic is at once used.

**Sublingual Growth in Infants.**—Samuel Amberg reports a case of this kind in a seven-months'-old boy. The structure of the growth hardly permits of any doubt that it is a product of an inflammatory process. The affection occurs most frequently in Southern Italy. The diagnosis presents no difficulties. The etiology remains obscure. The bacteriological examination thus far has not given satisfactory results. The theory of heredity is not sufficiently proven, neither is the congenital origin. Bad hygienic conditions of the mouth may be of importance. To the mechanical irritation produced by the lower incisions or by the hardening gum an important rôle is attributed. The idea that the sublingual ingrowth is an integral part of a definite serious disease does not seem to be well founded. The age at which the affection occurs seems to be confined to the first two years of life, starting from about the third month. It has been seen in a four-year-old child. The affection may disappear completely without any particular treatment, but the shortest and simplest way to accomplish a cure seems to be the excision. The prognosis is favorable.

**Concerning a Possible Etiological Factor in Tobacco-Alcohol Amblyopia Revealed by an Analysis of the Urine of Cases of This Character.**—G. E. de Schweinitz and David L. Edsall state that in recent times the pathogenesis of the toxic amblyopias in general, and particularly the alterations which are produced in the ganglion cells of the retina and in the optic nerve by the action of quinine, methyl alcohol, and filix mas, has attracted much attention. The writers present several cases of toxic amblyopia. In these cases there were evidence of a marked disturbance of digestion or metabolism, or of both. This disturbance may persist for a long time after the use of alcohol or tobacco has been stopped. Apparently treatment of this secondary nutritive disturbance will cause improvement in a persistent amblyopia. Undoubtedly toxic substances produced in the digestive tract, or in the course of metabolic processes, have, at least, a certain part in the production of the amblyopia in most of these cases and at times they are probably the direct cause of the

continuance of the symptoms when the latter do not disappear after alcohol and tobacco have been stopped. This view is entirely in consonance with the results of investigations concerning the manner in which other toxic effects of alcoholism are produced, and it also accords with our knowledge of the effects of some other chronic poisonings. The results in general in the cases studied show that there was an excessive secretion of enterogenous decomposition products in the urine; and in all there was a more or less marked mobilinuria.

**Sitophobia and Inanition, with Their Treatment.**—Max Einhorn says that by the term sitophobia we understand a condition in which too little food is taken on account of fear. This fear relates to pains or disagreeable sensations in the digestive apparatus arising after meals. To avoid these, patients prefer not to eat, or rather to eat as little as possible. Sitophobia is most common in chronic affections of the digestive system, accompanied by pains (gastralgia and enteralgia). Sometimes sitophobia arises in consequence of an abnormal sensibility of the gastric mucous membrane. It is advisable in some cases at the beginning of the treatment to diminish the sensitiveness of the digestive apparatus by bromides or similar drugs. These medicines are not essential, but rather bridge over the first few days by facilitating the carrying out of the directions in regard to rating. Another point of great importance is to improve the nutrition of the patient. The first change in diet must not be too great. If the patient has lived for a long time on fluid food only it is best to begin with liquid or semisolid food, as milk, beef-tea, raw eggs beaten up in milk, or broths, strained barley or oatmeal soups, gruels, and jellies. A sufficient quantity of nourishment must be taken. This diet should be increased daily by soft boiled eggs, zwieback, tender meat, mashed potatoes, white bread, butter, later, light vegetables, boiled fruits, etc., are added. As soon as the patient partakes of the usual articles of food, he should eat about as much as his neighbors at table, only taking more butter, and taking a glassful of milk and a slice of buttered bread between meals. With a diet like this we nearly always obtain an increase in weight.

**Chronic Cyanosis, with Polycythæmia and Enlarged Spleen: A New Clinical Entity.**—William Osler presents a group of cases, the condition of which is characterized by chronic cyanosis, polycythæmia, and moderate enlargement of the spleen. The chief symptoms have been weakness, prostration, constipation, headache, and vertigo. Six of the patients were males and three were females. All were in the middle period of life, the youngest thirty-five years and the oldest fifty-three years. There was nothing in the occupation or in the station of life of any moment. The viscidity of the blood is greatly increased. It is unusually dark. An extraordinary polycythæmia is a special feature of the affection. The percentage of hæmoglobin has been high, ranging to 165. In seven of the nine cases the spleen was enlarged. In four of these the enlargement reached nearly to the navel. In seven of the cases a trace of albumin was noticed, with hyaline, sometimes granular, casts. The specific gravity was usually low. The skin was pigmented in several of the cases. Our knowledge of the physiology of polycythæmia is still imperfect. To perfect this knowledge we need a careful study of all forms of chronic cyanosis with polycythæmia, particularly those associated with heart disease and emphysema; and a more accurate study of the blood in this class of cases. As increased viscosity of the blood, with resulting difficulty of flow, seems the most plausible explanation of cyanosis, it is especially important to test the viscosity by accurate physical methods, and to determine the relation of the number of corpuscles to the viscosity of the blood. The relation of the splenomegaly to the cyanosis and polyglobulism should be carefully observed. It may not be anything more than the effect of the chronic passive congestion Further investigation will determine whether this disease herein described is really a new one.

**An Aspect of Modern Pathology.**—Simon Flexner declares that the manner of action of bacterial agents upon red corpuscles, and our recently acquired knowledge of agglutination of cells in general, could not fail to suggest that certain kinds of thrombi are produced by a form of coalescence of corpuscles. The writer thinks it highly probable that agglutinative thrombosis will, in the near future, be recognized as an important pathological condition in man, and that a large number of the thrombi that arise in the course of infectious diseases and, doubtless, diseases of uncertain etiology will be discovered to have originated in agglutination. The experimental study of agglutination seems capable of shedding much needed light upon the subject of intravascular clotting in general. The writer has shown that the so-called coagula which appear in the heart in experimental ether and alien serum poisoning are not clots in a true sense, but merely masses of fused red corpuscles. That relation exists between extensive blood destruction and agglutinative thrombosis, the mode of action of ether and alien serum injections in producing rapid death quickly proves; and the essential identity of the agglutination produced *in vitro* and in the body by agglutinating and hæmolytic substances can easily be shown. The light which the study of agglutinins has shed upon the general subject of thrombosis has served also to add to the knowledge of certain forms of hemorrhage. That no necessary relation exists between thrombosis and hemorrhage can be shown experimentally by removing from rattlesnake venom its agglutinins for red corpuscles. When the hemorrhagic principle is left unaffected, and that no relation exists between hæmolysis and hemorrhage can be inferred from the action of cobra venom, which, while an active agent of blood destruction, causes but little hemorrhage. The existence of a substance having an especial affinity for vascular endothelium may be considered as proven for snake venom and ricin. For this principle, if it be a principle, the writer proposes the name of hemorrhagin, and looks upon it as a cytolysin for endothelial cells of blood vessels, the injury and destruction of which is the direct cause of the escape of blood into the surrounding tissues. Venoms which cause much hemorrhage exert a very destructive local effect upon the tissues. For this reason very little success has attended the efforts to produce an antitoxin for riper venom. Looked upon broadly, the corner-stone of modern pathology is toxicology. In many pathological conditions the leucocyte is the essential agent in bringing about absorption; and what is required to accomplish this end is not living leucocytes so much as large numbers of these cells, since autolysis proceeds independently of the vitality, as such, of the cells. The fate of pathological formations is dependent in large part on the numbers of leucocytes present within them.

*American Journal of the Medical Sciences, September,* 1903.

**Arguments in Favor of the Existence of a Separate Center for Writing.**—Hermon C. Gordinier reports a case of brain tumor in which voluntary speech was perfect, but complete agraphia was present throughout the entire course of illness. At the autopsy a new growth was found occupying the foot of the second left frontal convolution. On section it was seen to extend downward and inward in the centrum semiovale as far as the roof of the anterior cornu of the lateral ventricle, and forward to near the apex of the frontal lobe, involving almost exclusively the white matter of the second frontal gyrus. This case, the author says, seems to prove the existence of a separate and distinct cortical center for writing, having the same relation to writing movements as the motor speech center has to speech movements. This center is located at the base of the second left frontal convolution for the right-handed, and probably in the same location in the right hemisphere for the left-handed. Destruction of this center produces pure motor agraphia without aphasia or paralysis of either arm.

**Acute Myelogenic Leukæmia.**—Frank Billings and Joseph A. Capps report a case of this rare condition, occurring in a man sixty-eight years old, and have collected seven other cases from the literature, all the clear cases that they were able to find recorded. Most of the eight clear cases began abruptly in the manner of an infection; four of the patients had a throat inflammation, and in three there was a necrosis of the jaw or palate. With two exceptions, the glands were slightly or moderately enlarged, the cervical group being usually affected. The spleen was always large enough to feel. In only two instances, however, was the edge more than one finger's breadth below the costal margin. Hemorrhages occurred in every case in which the history was obtained. Fever was present in most cases, of an irregular, low-grade type. The anæmia was always severe and rapid, yet poikilocytosis was usually less marked than in a pernicious anæmia correspondingly severe. The white cells varied from 16,000 to 540,000, but the average count was much lower than is ordinarily noted in chronic myelogenic leukæmia. The blood picture, using these eight published cases as a basis, may be summed up as follows: (1) Anæmia, progressive and severe. (2) A large increase of white blood corpuscles (16,000 to 540,000). (3) A large proportion of the white cells (25 to 96 per cent.) made up of myelocytes, large mononuclear cells of the same size, and faintly granular large mononuclear cells (transitional cells). (4) Eosinophiles, mast-cells, and nucleated red corpuscles may be absent or present in varying numbers.

**Syphilis as a Cause of Chorea.**—L. Harrison Mettler reports a case of chorea in a boy the subject of inherited syphilis which led him to study the causative relation between syphilis and chorea. As a result of this study he

formulates the following conclusions: (1) Syphilis in rare instances is the cause of chorea, and should always be thought of as a possibility in the examination of every case. (2) Chorea may be the result of acquired or hereditary syphilis. (3) Most of the cases of syphilitic chorea are unilateral; belong to the prehemiplegic or posthemiplegic type of the disease; may or may not be associated with other signs of an irritative lesion · are not infrequently developed in hereditary syphilitics, and are to be attributed probably to a functional disturbance of an irritative sort in the cortical and ganglionic motor cells. (4) The existence and recognition of these two forms of syphilitic chorea—the focal and the generalized—support the inference that all forms of chorea are but the expression of one or more of a multiplicity of possible factors which may disturb the functional activity of the upper motor neurons, these factors being all the way from a gross lesion down to a molecular or chemical change not demonstrable with our present means of investigation. This conclusion leads to the further conclusion that chorea is not a disease but a mere symptom. (5) Syphilis, when determined as the cause of a case of chorea, should lead to the prompt and thorough treatment of the case as one of syphilis and not chorea.

**The Relation of Certain Adenocarcinomata to Atrophic Scirrhus of the Breast.**—J. Clark Stewart discusses first the question of the existence of a distinctive neoplasm of the breast which merits the title of atrophic or atrophying scirrhus, and comes to the conclusion that there is such an entity. These tumors, he says, resemble other forms of breast cancer in their early manifestations, but proceed slowly until the skin is involved, after which they seem to cease to grow and the ulcer shrinks and becomes hard and highly colored, giving origin to the lay name of "rose cancer." In this condition, either as an ulcer with slight discharge or as a dry, scaling depression, this form of cancer may persist for many years with little annoyance to the patient and practically no interference with her general health. Most of the older authors recognize this form of growth, and mention its comparative benignancy and the long periods which may elapse without other than local symptoms. The later authors, however, are inclined to ignore it, perhaps because modern surgical methods have tended to the removal of all breast tumors before reaching the stage at which the atrophic tendency would manifest itself. Regarding the advisability of operative measures for the removal of these tumors, he is decidedly of the opinion that they should not be interfered with, his argument being that experience has shown that such an operation quite uniformly fails to prevent recurrence and thus shortens life, as recurrences are much more malignant than the original growth. He believes that a more general histological study of these new growths would show that they are morphologically distinguishable from other malignant tumors of the breast, and that the presence of an adenomatous element would be found to justify their comparative benignancy.

**The Idiopathic or Essential Dropsies of Childhood.**—Arthur Willard Fairbanks reports nine cases of an unexplained œdema in children coming under his notice in the summer of 1902 He also gives notes of 72 cases reported in the literature, and says he has found mention of 96 additional cases. The characteristic feature of this condition is the appearance of œdema, in one or more parts of the body, without albuminuria or sedimentary evidence of organic disease of the kidneys; without clinical or post-mortem evidence of organic disease of the heart or kidneys. It occurs in children who previous to and during its presence are otherwise well; or it occurs, accompanied by symptoms more or less peculiar to it, in children previously and subsequently well, or, finally, it occurs immediately preceding, accompanying, or immediately succeeding some disease other than the organic conditions above mentioned. It may be acute, subacute, or chronic in its onset or course. The nine cases reported by the writer were apparently secondary in that they all occurred in the course of, or following some other pathological condition. In the nine cases reported by the writer, anæmia was present in four; but in half of these it did not appear until after the œdema. The temperature was subnormal in six of these cases at some time during the affection, but in only two cases persistently so. There was diarrhœa in seven. Of all the abnormal features that may be found associated with "essential œdema," the author says, far the most common is some disturbance of the gastrointestinal tract. This may, in a small percentage of cases of the very acute form, be due to a coincident affection of the mucous membrane, similar to that of the skin, but in the great majority of the cases it is probably an antecedent affection, often of great importance in the etiology of those cases of œdema in which it is present. Cyanosis is not a characteristic feature of the affection. The mortality of the affection is much greater in infants than in older children, being 34 per cent. in the former, but only 4 per cent. in children of two years and upward.

**Ulcerative Angina and Stomatitis Associated with the Fusiform Bacillus and Spirillum of Vincent.**—Jessie Weston Fisher reports two cases of this affection, one in a young man of twenty years, the other in a woman of thirty-six, and gives a résumé of the bacteriology of this affection, following Niclot and Marotte, as follows: The bacteriological characteristics of this affection of the mouth and throat is the almost constant combination of the fusiform bacillus and spirillum of Vincent. The fusiform bacillus is swollen at the center, with pointed extremities. It is generally straight, but is sometimes curved or bent upon itself and measures 6$\mu$ to 12$\mu$. It is encountered in irregular masses, often as a diplobacillus, and sometimes two are seen lying at an angle to each other. The motility has been questioned by a few, but is maintained by Niclot and Marotte. The bacilli stain readily with the basic stains, but are generally decolorized by Gram's method. The involution forms sometimes resist the decolorizing agent, and occasionally show a vacuolation or granulation, but never a demonstrable spore formation. The dimensions of the spirilla vary, but they are very long and of equal width throughout. They are observed singly, in groups, and are sometimes seen in an inextricable mass. Their motility may be retained for many hours, but diminishes rapidly on exposure to air or cold. The staining reaction differs from that of the bacilli only by the fact that the spirilla are invariably decolorized by Gram's method. When the disease process is superficial the spirillum may be absent, but in the deeper lesions the combination of bacillus and spirillum is invariable. In the superficial parts of the ulceration one finds Vincent's bacillus and spirillum associated with the streptococcus, pneumococcus, colon, and Klebs-Löffler bacillus, but in the deeper parts only the bacillus and spirillum in their characteristic combination are found.

## Surgical Suggestions.

**Chronic Specific Ulcer.**—In addition to general treatment, thorough scrubbing with brush, and soap and water, followed by bichloride solution, and a wet bichloride dressing held in place by an elastic woven bandage. After the wet dressing has been on a few days a mercurial ointment may be substituted for it.—H. W. CHENEY.

**In Traumatic Ulcer** the patient must be sent to bed and kept there for a considerable time. If the edges of the wound are sphacelous, the necrotic tissue must be trimmed away and the ulcer thoroughly but gently cleansed with hot saline solution. A large gauze dressing is to be changed three times a day and kept constantly wet with saline solution. After the suppurative process is stopped and the granulations look healthy, the patient, if a laboring man, is shown how to apply a large gauze dressing, which is wet twice a day with saline solution, this dressing being covered with protective, and a rubber bandage carefully applied over the whole dressing.—J. O. COBB.

In **Indolent Ulcer** wet bichloride compresses, applied after thorough scrubbing or cleaning, followed by application of the woven, elastic bandage. The wet dressing should be changed twice a day for three or four days, and then, after cleansing with hydrogen peroxide, an ointment composed as follows:

| | |
|---|---|
| Ichthyol..... | |
| Balsam of Peru.....āā | gr. xxiv |
| Vaselin..... | ʒi |

Operation is usually required in eczematous and varicose ulcers—in the latter, tying of the saphena.

—CHENEY.

**Puerperal Fever.**—In conclusion I wish to state emphatically that "puerperal fevers" will practically disappear when doctors, nurses, and midwives learn that the woman in labor and immediately after should be treated upon the same rules of antisepsis as govern the surgeon in the most extensive operation.—EMORY LANPHEAR.

# Book Reviews.

A Manual of Surgical Treatment. By W. Watson Cheyne, C.B., M.B., F.R.C.S., F.R.S., Professor of Surgery in King's College, London, Surgeon to King's College Hospital, etc., etc., and F. F. Burghard, M.D., and M.S. (Lond.), F.R.C.S., Teacher of Practical Surgery in King's College, London, etc. In seven volumes. Volume VII. The Treatment of the Surgical Affections of the Rectum, the Liver, Pancreas and Spleen, the Genito-urinary Organs, the Breast and the Thorax. Philadelphia and New York: Lea Brothers & Co., 1903.

The present volume brings finally to completion a work which fulfils its avowed purpose better than any in the English language with which we are familiar. As in previous volumes, the authors have sought a certain amount of condensation in order to bring their enormous subject within bounds, and they have endeavored to select for full discussion only those methods and ideas which seem to them most desirable. The title page tells to what departments of surgery the present volume is devoted. The chapter upon diseases of the rectum is practical and sound, and that on the surgery of the biliary passages noteworthy as drawing considerably from American sources, but it is perhaps almost too much condensed. We agree with the authors in their advocacy of a more or less expectant plan of treatment during the acute symptoms of gonorrhœa, especially as regards the urethral canal itself. The chapter on tumors and other diseases of the breast indicates that the authors are believers in radical surgery in this department, and they express themselves as satisfied with their experiences when other methods are considered. It is unnecessary to enumerate specially all the features of this concluding volume, but we are grateful to its authors for having placed in our possession such a comprehensive and convenient work.

Die Pathologie und Therapie der Unfruchtbarkeit des Weibes. Von Dr. Ferdinand Schenk, Assistant der k. k. Deutschen Universitäts-Frauenklinik, Prag. Berlin: Verlag von S. Karger, 1903.

This is a pathological and therapeutic treatise on the conditions which cause sterility in women. After a preliminary review of the anatomy and physiology of the female generative organ, the author divides the causes of sterility into three groups—developmental defects, new growths, and inflammatory processes—which he proceeds to discuss. Therapeusis is reviewed in the same systematic way, and a few pages are filled with references to the literature of the subject.

On Siphonage and Hydraulic Pressure in the Large Intestine, with Their Bearing upon the Treatment of Constipation, Appendicitis, etc. By Ralph W. Leftwich, M.D., late Assistant Physician to the East London Children's Hospital, etc. New York: William Wood & Company, 1903.

This is an interesting little monograph in which the author seeks to prove that the human colon acts to a great extent like a siphon in emptying itself of its contents. The arguments are clear and reasonable enough to make us agree with the conclusions. Some space is devoted to the bearing of this siphon action upon pathological conditions.

A Textbook of Surgery for Students and Practitioners. By George E. Brewer, A.M., M.D., Lecturer on Clinical Surgery at the College of Physicians and Surgeons, Columbia University, etc., etc. Illustrated with 280 Engravings in the Text and Seven Plates in Colors and Monochrome. New York and Philadelphia: Lea Brothers & Co., 1903.

This volume is one of a class already large and rapidly increasing. It contains little with which to find fault, and little to praise except as it represents great industry on the part of its writer, who has clearly taken much trouble to make his book meet the requirements of the class of readers for whom it is intended. It seems to be unavoidable at present for the man who has reached even moderate prominence in the work of instructing students in any department of medicine to write a textbook, and it follows from this, that almost all modern textbooks are mere compilations, have no particular features of superiority over others of their class, and can appeal only to the necessarily limited number of readers attracted by more or less personal reasons. This is not necessarily a specially undesirable state of affairs, but it lowers the average value of the books, which in the nature of the case cannot embody any matter of importance to the science of medicine. The present volume is systematically arranged, it contains all that the student of medicine need become familiar with, and it is presented in attractive form, with good illustrations. We cannot say that it makes a niche for itself, or that any predecessor is likely to lose ground in the presence of a new competitor.

Success in Dental Practice: A Few Suggestions Relative to the Most Approved Methods of Conducting a Practice. By C. N. Johnson, M.A., L.D.S., D.D.S., etc., etc. Philadelphia and London: J. B. Lippincott Company, 1903.

This little volume contains a plea for the introduction of business-like and systematic methods into the practice of dentistry, and much that is said in it applies to the practice of medicine. It is intended chiefly for young men, and the advice in it is, as a rule, good, though sometimes awkwardly put, and interspersed with unnecessary anecdotes.

Protozoa and Disease. By J. Jackson Clarke, M.B.; Author of "Surgical Pathology and Principles," etc. New York: William Wood & Co., 1903.

In this book of 175 pages the author gives an excellent presentation of the subject, the text being illustrated by numerous pertinent figures. Starting with a necessary preliminary chapter on cytology (describing the essential intracellular structures, the mechanism of cell division, etc.), the author gives a detailed sketch of the several groups of the sporozoa, and their share in the production of disease. In each case the whole life cycle is followed and illustrated, thus bringing before the student and general practitioner data that were not long since to be found only in "the literature." Any one who wishes to take up this line of work will find here directions as to where the various microscopical forms are to be found, usually with illustrations of their hosts, which is, of course, an aid in obtaining specimens. A chapter is devoted to the diseases to which the protozoa themselves are liable, and another describes the various processes of technique which have yielded the best results in this field. The question of the *modus operandi* of infection is also kept in view, and the infection circle is brought out. On the whole this little work furnishes an exceedingly useful introduction to the subject.

Tumors, Innocent and Malignant, Their Clinical Characters and Appropriate Treatment. By J. Bland-Sutton, Surgeon to the Chelsea Hospital for Women, Assistant Surgeon to the Middlesex Hospital, London. Third edition. Chicago: W. T. Keener & Co., 1903.

This volume bears the same relation to the general subject of pathological growths that Treve's book holds to anatomy. Perhaps the most radical step forward in this new edition is the entire elimination of the term "Epithelioma." Throughout the book it is replaced by the phrase "squamous-celled cancer." One cannot but regret that a further exaction has not forced aside the generic "cancer" and placed in its stead the more precise and technical word "carcinoma."

Of the arrangement of this volume we have nothing but praise. More than ever before, Mr. Sutton has shown the important and dominating pertinence of comparative pathology. As he well says, "there is a material basis for these significant lines." "The softest dimple in a baby's smile springs from the whole of past eternity, tasked all the sum of things to bring it there." "The grandest discovery ever made by man about himself is the doctrine of evolution." It is, therefore, not surprising that the most interesting part of the book is that which deals with congenital malformations.

Further improvements to be commended are the restoration of the section on echinococcus colonies, and the introduction of a chapter on the deadly deciduomata.

It is to be regretted that an attempt should have been made in this work to outline the "appropriate treatment" of tumors. From our standpoint such outlines are often crude and incomplete. On page 281 the discussion of the treatment of gastric carcinoma is weak—in no way up to the standard of the general matter. On page 303 the treatment of prostatic obstruction is not modern, nor is any prominence given to the successful transplantation of the ureters while considering the treatment of malignant tumors of the bladder.

If all suggestions as to treatment were eliminated from this work and the space given to that descriptive text of which the author is so great a master, the change would be very welcome.

Vorlesungen über Magen und Darmkrankheiten. Von Dr. Friedrich Crämer, I. Heft. Magenerweiterung. München: J. F. Lehmann, 1903.

This chapter on dilatation of the stomach, which forms a portion of the work on Digestive Diseases of Dr. Crämer, is very well written. The author mentions a case of ischochymia which was caused by cherry pits occluding the pylorus. He also describes another case of ischochymia in which the symptoms were caused by chronic appendicitis. Removal of the appendix resulted in a perfect cure of the gastric symptoms. With regard to the diet in dilatation of the stomach caused by obstruction

of the pylorus, Crämer recommends solid foods and restriction of the quantity of fluids. This view does not correspond with that held by Einhorn, Boas, and others, who recommend the strictly liquid régime at the beginning of the treatment. As a whole the present monograph can be highly recommended.

Disease of the Pancreas. By Eugene L. Opie, M.D. Philadelphia and London: J. B. Lippincott Co., 1903.

The diseases of the pancreas are still difficult of recognition during life. Any additional knowledge serving to clear this obscure field of internal medicine must be heartily received. In the present work Opie, well-known for his researches on pancreatic diseases, has succeeded in giving to the medical profession a clear and concise treatise on the pathology of the pancreas. The association of pancreatic disease with alterations of the bile passages has been noted by a number of clinicians, but especially by Opie himself. This association is frequently found in hemorrhagic inflammation of the pancreas. The common bile duct and the duct of Wirsung uniting to form the diverticulum of Vater before they reach the duodenum, changes in the one will be easily transmitted to the other, thus producing secondary lesions of the liver or pancreas. A small calculus only partially filling the ampulla of Vater can convert the two ducts into a continuous channel, while a larger stone might simultaneously obstruct the duodenal orifice of the diverticulum and the orifices of the two ducts which enter it, thus damming back bile and pancreatic juice upon their respective glands. The author has experimentally shown that bile entering the pancreatic duct is liable to cause deleterious effects of this gland. The injection of five cubic centimeters of bile into the pancreatic duct caused hemorrhagic inflammation of the gland in four dogs, two of which died within twenty-four hours after the operation. In these experiments death did not follow the use of smaller amounts, and the changes produced in the organ were less widespread and severe. In every case necrosis of the adjacent fat accompanied the lesion of the pancreas, and in two instances in which death occurred spontaneously foci of the necrosis were abundant and disseminated. As a whole, the book can be recommended as an excellent guide on the diseases of the pancreas.

The Diagnosis of Diseases of Women. By Palmer Findley, M.D., Instructor in Obstetrics and Gynecology, Rush Medical College; Assistant Attending Gynecologist, Presbyterian Hospital, Chicago. Philadelphia and New York: Lea Brothers & Co., 1903.

This treatise is well adapted to the needs of both the student and practitioner, for in it the former can readily find the essential facts, while the latter will not be disappointed if he looks for detailed information on any special topic. It should be remembered that this is not a textbook of the diseases of women, but, as the title indicates, deals only with diagnosis of such diseases; nevertheless the mode of obtaining this all-important and fundamental knowledge is presented so vividly that the therapeutic indications become obvious, and the reader often fails to notice the omission of the treatment. The specia' feature of the work, and one which gives it a peculiar place in English medical literature, is the thorough discussion of the morbid anatomy, and the great prominence given to the microscope as an aid in clinical diagnosis. This was done because the author believes that the recognition of the pathology of the pelvic organs constitutes, in large measure, a diagnosis. An entire chapter is devoted to the consideration of the microscopical examination of scrapings and excised pieces, and the text throughout is embellished by over 250 illustrations, many of them colored representations of microscopical specimens. The book is divided into three parts, the first dealing with general diagnosis, the second with special diagnosis, and the third with the diagnosis of diseases of the urethra, bladder, ureters, and kidneys.

Recherches Anthropométriques sur La Croissance des Diverses Parties du Corps. Détermination de l'Adolescent type aux différents âges pubertaires d'après 36,000 mensurations sur 100 sujets suivis individuellement de 13 à 18 ans. Ouvrage couronné par la Société d'anthropologie de Paris, 1902. (Prix Broca.) Par Docteur Paul Godin, Médecin-Major de 1re Classe: Médecin-Chef de l'Hopital (Salles Militaires) de la Fère; Lauréat de l'Académie de Médecine. Préface par M. le Dr. L. Manouvrier, Professeur à l'Ecole d'anthropologie de Paris. Paris: A. Maloine, 1903.

Godin presents in this superb piece of work, the results of his very careful and painstaking researches. He speaks of the medico-military value of such work. He then discusses mensuration and anthropometric technique. The subject of anatomical correspondences of various parts of the body is taken up—for example, correspondence of the elbow, of the umbilicus, and of the upper border of the iliac crest in the axillo-trochanteric line. The various parts of the body are studied in detail, and the different diameters, circumferences, and weights are compared. The signs of the appearance of puberty, with the value of each, are considered. Various tables are presented, showing the numerous measures that have been taken, and a valuable bibliographical index is appended.

Ambulance Work and Nursing. A Handbook on First Aid to the Injured, with a Section on Nursing, etc. Chicago: W. T. Keener & Co., 1903.

Perhaps no subject has been of more popular interest of late years than that of first aid to the injured. The author presents first a chapter on the skeleton. This is followed by a brief description of the muscles, tendons, nervous system, the eye, ear, skin, the principal organs of the body, the blood, arteries, and veins. Hemorrhage is then considered, and clear and concise descriptions are given for the control of bleeding in various parts of the body. The different kinds of wounds are then described, and an excellent chapter follows on bandaging. The text is so profuse'y illustrated that the veriest tyro would have no trouble in following the directions. The treatment of special and common fractures concludes this part of the work. Next, the author reviews respiration or breathing, insensibility, burns, scalds, poisoning, foreign bodies in the eyes, ears, and nose, and the means of transportation of the injured; ncluding stretcher exercises. In the last part of the book, nurses and nursing, the choice of a sickroom, beds and bedding, the metric system, enemata, poultices, cooling drinks, and massage are all included. Taken all in all, this book is a happy addition to this part of medical literature.

Surgical Diseases of the Abdomen, with Special Reference to Diagnosis. By Richard Douglas, M.D., formerly Professor of Gynecology and Abdominal Surgery, Medical Department Vanderbilt University, Nashville; Ex-President of the Southern Surgical and Gynecological Association; Fellow of American Association of Obstetricians and Gynecologists; Member of the British Gynecological Association, etc. Philadelphia: P. Blakiston's Son & Co., 1903.

This is a valuable addition to surgical literature, which will no doubt be welcomed by a wide circle of readers. The section on Typhoid Perforation furnishes an excellent example of how such subjects should be treated. The chapter, while generously conservative, is as up to date and as concise as the best journal monographs of the day. Indeed, in the entire work the author has gathered and bound together the best of the entire literature of the surgery of the abdomen for the last ten years, and given us a panoramic display, colored in the light of his ripe judgment and experience.

It is not to be expected that such a work could come fresh from the press without presenting a number of statements and views which in the second edition may call for reconsideration. On page 104 is found the following opinion: "Absence of hydrochloric acid in cancer of the stomach has no especial significance. . . ." On page 107 we read, "Examination of the stomach-contents, showing the presence of lactic acid and the absence of hydrochloric, is practically conclusive of cancer. Exceptions to this rule are quite rare." Such statements weaken an otherwise strong chapter. Enough credence is not shown in the growing and widespread opinion that ulcer is the most important etiological factor in gastric carcinomatosis. It may properly also be suggested that the classification of gastric carcinomata, given on page 94, is not as up to date as the standard of the book demands. A further criticism might be that too much attention is given to the diagnostic value of McBurney's point, which, on page 268, is erroneously described as a "subjection symptom."

But these are slight errors which do not seriously affect the value of the book.

The Praxis of Urinary Analysis. A Guide to the Chemical Analysis of Urine. With directions for Preparing Artificial Pathological Urines for Practising the Various Tests and an Appendix on the Analysis of Stomach Contents. By Dr. Lassar-Cohn, Professor in the University of Koenigsberg. Authorized Translation from the Author's Enlarged and Revised Second Edition, by H. W. T. Lorenz, A.M., Ph.D. (Berlin), Late Instructor of Organic Chemistry in the University of Pennsylvania. First Thousand. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1903.

The fact that a second edition of this book has been issued within six months after its first appearance, is proof of its cordial reception by the profession. Urinary analysis is considered in three sections: Qualitative tests, quantitative methods, afid normal urine. Analysis of stomach contents is then taken up. The subject matter is presented in a very concise but practical manner, making the book very helpful to the busy practitioner.

## THE AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

*Seventeenth Annual Meeting, Held at Washington, D. C., May 12, 13, and 14, 1903.*

**Special Report to the Medical Record.**

(Continued from page 438.)

*Friday, May 14, 1903—Third Day,*

**The Use of the Cystoscope in the Study of Prostatic Hypertrophy.**—Dr. HUGH H. YOUNG of Baltimore presented this communication. He said that the use of this instrument in the study of prostatic hypertrophies had been doubted by many, many declaring it valueless. With the cystoscope he had had manufactured one was enabled to study the prostate from every side. The ordinary cystoscope had a right-angled prism. The instrument he had devised enabled one to look backward. In order to get a view of the entire prostatic orifice it required six different pictures, each picture representing one-sixth of the circle, or 60 degrees. Instead of a compound prism he used a four-sided prism, which enabled him to look backward and view the prostatic lobes. The object of his paper was not to demonstrate his instrument, but to show how it was possible to make an ordinary cystoscopic examination tell us the condition of the prostate in ordinary cases of prostatic hypertrophy. He exhibited a series of charts showing the pictures given by the six different turns of the cystoscope, and demonstrated how one could tell the kind of enlargement from a study of these pictures. He had a series of pictures taken of 120 cases which were of great value to him in his work in this connection. On account of imperfections in the instrument due to poor instrument-makers in this country his results had not been entirely satisfactory.

Dr. W. K. OTIS of New York said that one of the principal objects in a cystoscope was to have sufficient room for light, and, therefore, his instruments were larger than those usually employed, about 30 F. He believed that a careful and methodical examination of the prostate still required more practical experience in order that an idea might be formed of the conditions presented.

**Report of a Case of Filariasis.**—Dr. F. TILDEN BROWN of New York reported this case. He said that a mistake in clinical diagnosis had been made in this case, but he was fortunate enough, in the microscopical examination which followed the operation, to find numerous embryos in different developmental stages of what he took to be Filaria bancrofti. The patient's blood failed to show the embryo, and he thought this might, in part, be explained by the supposition that the orchidectomy had removed all the female worms, if, in fact, more than one had originally been present. The patient was a German, thirty-four years old, in the United States Marine Hospital Service, and he had been stationed at Porto Rico for the past two years and had had no fever or illness of any kind. During the past two months he noticed an enlargement and slight tenderness of the left testis. The possibility of its being a barrier to re-enlistment led him to enter Bellevue Hospital, New York City, for operation. Examination showed a moderate enlargement of the left testis, and it was difficult to determine whether the slight but tense effusion in the tunica vaginalis was responsible for the increase in size or not. A small nodule the size of a marble, slightly tender, was felt where the midbody of the epididymis was apposed to the testis. Which of the two organs it involved could not be determined. The spermatic cord was found to be larger than its fellow. The vas was thicker, but not beaded. He had had no gonorrhœa for ten years and never a swollen testicle from this cause or from traumatism. A diagnosis was made of tuberculous epididymitis and the patient requested that the testis be removed. At the operation fully an ounce of straw-colored fluid was found occupying the tunica vaginalis. This sac, together with the testicle, the lower one-third of the cord, and a considerable more of the vas was removed. Palpation of the specimen now showed a small nodule occupying not the epididymis but the rete testis just underlying it. In cutting into the lesion a compact fibrous periphery was noted and, in its center, a yellowish-white semifluid material, somewhat resembling tuberculous débris. A small amount of the adherent material was placed upon a slide and, when examined microscopically for tubercle bacilli, small worm-like forms were seen. Another slide treated with eosin glycerin showed a number of field clusters of lumbricoids having the characteristics of the filaria sanguinous hominis. The larvæ were granular and surrounded by a loose fitting hyaline membrane. Immature forms were of oval shape, and the intermediate forms showed the embryos coiled and doubled in a larger oval sac. Dr. Brown concluded that when cutting into the nodule he may have opened a dilated lymph vessel or space, the abiding place for the adult female filaria; the knife had probably severed this worm in several places, and in scraping it the uterine canals had been compressed and more or less emptied of their contents, and this might account for the great number of embryos found in the different developmental stages.

**Remarks on Surgical Treatment of Chronic Bright's Disease by Renal Decapsulation.**—Dr. RAMÓN GUITÉRAS read this paper. He said that through the efforts of Dr. George Edebohls an operation for the treatment of chronic Bright's disease had been launched, and had caused general interest among surgeons in both America and Europe. This operation consisted either in partially decapsulating one or both kidneys and fastening the denuded surfaces to the posterior abdominal wall, or of fully decapsulating these organs and replacing them in their fatty capsule. The former of these procedures had been in a great measure superseded by the latter, although in his mind there was still a question as to which was the better. At a meeting of the American Genito-urinary Association, held in Atlantic City last year, he had presented a paper entitled, "The Operative Treatment of Chronic Bright's Disease," in which he had reviewed the literature of total decapsulation and had reported two cases of his own, one of total decapsulation, the other of partial stripping of the capsule, together with fixation of the organ to the abdominal wall. He had begun work last year as a skeptic, and had refused to operate upon many cases referred to his hospital wards, which he would now consider deserving of operative interference. His experience and the growing favor with which this operation was regarded by many of the leading surgeons led him to send a circular letter to the leading surgeons in order to ascertain their experience in this line of renal work. From the answers that he received from about 150 of these letters it appeared surgeons were about equally divided pro and con on the operation. The theory as to the benefit to be derived from this operation was that the circulation of the kidney was increased by forming an anastomosis with the tissues of the abdominal wall, or the fatty capsule, and thus functional activity was materially aided. Some went so far as to argue that the kidney after this operation could be compared with the lungs, as in these latter organs the bronchial arteries and the pulmonary anastomose, and some of the return venous blood from the bronchial vein emptied into the pulmonary veins. Whether or not a corresponding result was obtained in the kidney would be considered later in concluding. The conditions which were considered favorable for the operation were movable kidney with casts and albumin, movable kidney associated with nephritis, chronic interstitial nephritis, and diffuse nephritis. Over 100 of these cases had been reported, 16 per cent. of which had been spoken of as cured, 40 per cent. as improved, 11 per cent. unimproved, and 33

per cent. died. The cases which were most favorable for this procedure were those of chronic diffuse nephritis, of which there was a mortality of 75 per cent. Many of these patients were operated upon in extremis, when they were suffering from general anasarca. Nearly all of them had been suffering from uræmic symptoms, while 75 per cent. of them were œdematous. Many cases of albuminuria and cylindruria were not, properly speaking, Bright's disease; although if the causes that produce them were kept up long enough chronic nephritis might occur. Movable kidney was often associated with this condition, as there was a congestion present due to the tension on the renal vessels. This might be absolutely cured by nephropexy. In order to have a true nephritis we must have an inflammation or degeneration of the blood vessels, interstitial tissue, the glomeruli or the linings of the tubules of the kidney. Such changes always occurred in both kidneys, although they might vary in degree in different organs. This was a generally acknowledged fact by pathologists, and had been proved by Kümmel and Strauss in their investigations by means of urethral catheterization. He had looked over the records of 500 autopsies ascribing deaths to chronic Bright's disease, and in not one instance could it be said that the nephritis was unilateral, and in only 14 had the reports indicated that one organ was more involved than the other.

Nephritis in both kidneys might often be found existing in connection with movable kidney on one side. In this case nephropexy might improve the patient's condition by arresting the process, although it might not cure the disease when pathological changes had taken place to the same degree that a patient was cured of typhoid fever, pneumonia, or some other disease of this nature when resolution had taken place. Pousson believed that there was a sympathy between kidneys as between eyes, and an operation on one would frequently relieve the condition existing in the other. This idea was applicable to cases of nephritis that had come under his observation, in which he found by ureteral catheterization all the evidences of nephritis of both kidneys, and yet some time after nephropexy of one organ the common urine coming from both organs showed no evidence of Bright's disease, although the percentage of urea did not come up to the normal in the twenty-four-hour specimen. In chronic nephritis tension was relieved by splitting the capsule. He did not believe that it was necessary to decapsulate the organ entirely in order to afford relief. Those who had split the capsule of the kidney over its convexity would remember the gap which developed at this point when this covering had been holding the organ tightly and this gland had been congested. M. Mongour was of the opinion that diminishing the renal venous tension would increase the arterial tension and thus favor the flow of urine. Splitting the capsule and, to a certain degree, decapsulation would also, by diminishing the blood tension, take the strain off the heart by necessitating a diminished flow on its part. It was still a question with the author whether it was better to decapsulate the kidneys partially and to make them fast to the abdominal wall, or fully to decapsulate and return them to the fatty capsule. From the firm adhesions which he had seen between the kidney and the posterior abdominal wall and the scant vascularity, he had observed in the fatty capsule he felt that the former method might later be the one of choice. Again, it was not well known just how much of the blood supply could be obtained from the fatty capsule, and he had not noticed reports of the estimate of the amount of additional circulation derived in this way from autopsy records. Experiments on dogs, according to Dr. Johnson of San Francisco, tended to show that the blood supply obtained from the fatty capsule was very meagre. Dr. Johnson said that the renal capsule consisted of two layers, the outer of which is thicker. In decapsulation the outer always came away, leaving the inner lacerated, but adherent. After decapsulation a thin exudate appeared on the surface, which, with the remains of the inner layer of the old capsule, became a fibrous investment, resembling macroscopically the normal capsule of the gland in that it stripped readily and became more and more fibrous. In some cases it was thicker and in some cases thinner than the original. Generally it was thicker, after two months, according to Albarran and Bernard. Up to three and one-half months it was simply a fibrous mass, when it could be differentiated into two layers. In no case was there a considerable anastomosis between the renal and the perineal blood channels. Even if the relation of a dog's kidney to the surrounding tissues was not the same as those in man, it was still probable that the reconstruction of the capsule was the same, and this reconstruction in three and a half months would probably indicate the renewal of tension in the kidney, and consequently the recurrence of the symptoms. It might also account for the many deaths that occurred after this period. It seemed to him that as long as the patient with chronic Bright's disease was comfortable and ridding himself of sufficient solids we should treat him in a conservative way by means of diet, waters, and medicines. But if the process was advancing rapidly, and there was fear of the heart becoming overtaxed, the time had arrived for operative interference. In cases of interstitial nephritis operated upon the albumin and casts might disappear, but the amount of solids given out in the urine might still remain the same. In almost all cases reported there had been some uræmic symptoms and varying degrees of œdema, while in a number of cases there had been general anasarca. In the first group of patients, those having some uræmic symptoms or chronic œdema an operation could be resorted to in case medical treatment was of no avail. In cases of anasarca, especially if the heart was very bad, it was a question whether one should operate or not. Some have said that this was the time that operation was imperative, but the histories give a mortality of 50 per cent. in these cases, 25 per cent. were unimproved and finally died, and but 25 per cent. were cured or improved. He had never had the courage to operate in these cases. After all operations the patient must be kept quiet for some time and treated medically. In chronic nephritis when the patient was passing little or no urine, operation was imperative. Drs. Marx and Whitacre had operated in such cases with marked success. On the other hand Rocky operated upon a case for suppression and lost the patient in twenty-four hours. Freeman operated upon a patient who was passing a fair amount of urine and in good condition and the patient died in eighteen hours of suppression. In order to understand these cases better the separate urine from each kidney should be obtained by urethral catheterization and examined. It must be remembered that operation for chronic nephritis by decapsulation was as yet a new procedure and might require many modifications. We could remember when hysterectomy, prostatectomy, intestinal anastomosis, and even hernia were considered difficult and dangerous operations. Therefore we might hope that sometime these hopeless cases might be cured radically and without danger by the surgeon's knife

Dr. GEORGE M. EDEBOHLS of New York said that he had not yet reached any definite conclusions regarding the value of this operation, and certainly not as definite as those reached by Dr. Guitéras. It would be from two to five years before it would be known exactly just what the operation, or its modification, would do for these patients suffering from Bright's disease. He said he would not go into the subject fully because his views had already been published in the MEDICAL RECORD, March 28, 1903. Out of fifty-nine patients operated on eleven could safely be considered in the ranks of permanent cures. Before a patient should be placed upon the list of cures he said

he should be free from albumin and casts for a period of six months at least, and continuously. The improvement that had followed this operation had been so uniform that it offered encouragement to continue the work. As one absolute result, he mentioned the increased excretion of urea; where the output before operation may be below 100 grains per day it would be increased to 500 grains per day within four or five weeks. In his published articles he had tried to subdue his enthusiasm, but his results had been better than pictured; every patient had been relieved of their headaches, backaches, the circulation had been improved, the heart's action improved, and some patients seemed to pass from an apparently hopeless condition to one of comfort. The operation itself he considered to be a very simple one. If Bright's disease affected a movable kidney he would not anchor that kidney unless it presented symptoms that were due to that condition; if such symptoms did exist he then anchored it. When such kidneys are returned to their fatty beds often they become more or less fixed, due to the infiltration about them. Two weeks ago he was able to examine the kidneys removed from a patient on whom he had performed this operation four months prior. This death was independent of any kidney operation. Serial sections were made, and enormously dilated and enlarged blood vessels were shown which penetrated from the fatty capsule through the capsule proper into the kidney substance. The capsule proper was shown to be reproduced. Further findings in this examination will be published later.

Dr. EUGENE FULLER of New York reported two cases he had operated upon; in one there was a marked amelioration of the symptoms; in the other no report could be made because the patient passed from his view.

Dr. ARTHUR T. CABOT of Boston reported favorably regarding the operation. He thought we should discriminate more in regard to the selection of cases for operation.

**Subparietal Injuries of the Kidney.**—Dr. FRANCIS M. WATSON of Boston read this paper. He said that a personal experience of five cases of subparietal injury to the kidney had recently led him to make a thorough study of the subject, in the course of which he had collected, formulated, and analyzed clinical data of 660 cases, which included all previously published cases of importance. This investigation brought to his notice a number of points which had hitherto received little or no attention.

The kidney might be ruptured by muscular action alone. This occurred in ten instances. Sometimes the accident was produced by what seemed to be a very inadequate force. He referred to an instance of a woman whose kidney was torn by the forcible grip of her husband's arm around her waist while waltzing with her. Blows or falls upon the front of the abdomen not infrequently cause rupture of the kidney as the sole result of the trauma. There were reported twenty such instances in which the violence was reported to have fallen upon the anterior wall of the abdomen; this did not include the numerous other cases in which a crushing force passed over the abdomen while the patient was lying upon his back, etc. When there was but one intraperitoneal organ injured, in addition to the kidney, it was always upon the same side as the latter. The rarity of associated lesions of the small intestines, or its mesentery, or the transverse colon, the omentum, and the non-occurrence of injury to the stomach, in these cases of subparietal rupture of the kidney, was striking.

In quite a number of the cases of lacerated kidney peritoneal irritation, as shown by vomiting, abdominal distension, tympanites, muscular rigidity, loss of peristalsis, etc., was not present. This was shown in 18 cases.

He referred to the interesting points regarding hæmaturia. In several instances there was a delay of from one to eleven days before the occurrence of this symptom. The absence of this symptom was noted in 7 out of 340 cases, and this might be referable to any of the following causes: Tearing across of the pelvis, ureter, or renal vessels, complete disintegration of the kidney, thrombosis of the blood vessels, and obstruction to the ureter by blood clot and renal débris. That hæmaturia could persist for a long time without fatal results was shown by 6 cases in which it persisted for 56–46–42–28–21–18 days respectively, the patients all recovering. Tumor in the loin was noted in 103 out of 486 cases that were uncomplicated. In 41 it represented a traumatic hæmatoma. In 26, traumatic hydronephrosis. In 32 perinephritic abscess. In 4, treated expectantly, the tumor was in all probability a retroperitoneal hæmatoma. The average time of appearance in the cases of hydronephrosis was 24 days after the receipt of the injury, as compared with 15 days in the cases of the perinephritic abscess. In 25 of the cases in which the tumor was retroperitoneal hæmatoma, it developed within a couple of hours after the injury. Another point of interest with regard to the tumor of the loin, when it represented a perirenal hæmatoma, was that increase in size during the first twenty-four hours, or even forty-eight hours, after its appearance, if it took place gradually, was not necessarily a dangerous indication. Another feature was the length of time the tumor could be present and not become infected; in 7 cases of perirenal hæmatoma, without infection, the duration varied from two weeks to one month, and the same was true in 4 of hydronephrosis, in two of them, two months and the other two, three months. Hemorrhage was responsible for the largest number of deaths which occurred in connection with subparietal injuries of the kidney. Out of the 486 uncomplicated cases of the series collected by him there were but ten of the total number of 112 deaths which were due to retroperitoneal, or intrarenal hemorrhage alone, or a little less than 5 per cent.—23 per cent. being the general mortality from all causes of the whole number of uncomplicated cases.

There were altogether 594 cases in which the nature of the treatment was described. Of these 108 had associated injuries connected with them, and 486 were uncomplicated. The results of treatment of these 594 cases were as follows; Treated expectantly, 329; deaths, 127, or 38 per cent. Operations other than nephrectomy, 105; deaths, 12, or 11 per cent. Cases treated by nephrectomy, 160; deaths, 44, or 27 per cent. Bearing in mind both the statistical showing made with respect to different methods of treatment and the various data of other sorts already mentioned, he said the following tentative inferences seemed justifiable, and that all cases should be treated operatively in which one or more of the following conditions were presented: (1) Hæmaturia sufficiently abundant and persistent to produce the signs of serious hemorrhage. (2) The presence of a rapidly increasing tumor or area of dulness in the loin. (3) The development of a tumor in the loin ten days or more after the receipt of the injury. (4) Immediate operation, when the presence of free fluid in the abdominal cavity, or symptoms pointing to peritonitis, or other intraperitoneal lesion, occur. He believed the operation of choice in all cases in which there was good ground for believing that intraperitoneal hemorrhage or other grave condition existed, was that of exposing the kidney in the loin by a lumbar incision.

Dr. EUGENE FULLER of New York reported an interesting case. A butcher's helper had one-quarter of a beef fall on his shoulders, from which he experienced considerable pain on one side and increased frequency in micturition, and blood in the urine shortly after the injury. He had been around to different places and cystoscopic examinations revealed nothing. Dr. Fuller cut down upon a tumefied mass and found an immense cold abscess holding over a pint of thick pus. The walls of the abscess cavity were three-quarters of an inch in thickness and very dense and fibrous. No kidney could be found. He thought that, at the time of injury, a rupture of the kid-

ney occurred with extraperitoneal clots of blood, which gradually broke down into pus; the back pressure probably destroyed the kidney.

**Observations on the Effect of Catheter Drainage on the Function of the Kidneys in Interstitial Nephritis and Pyelonephritis.**—Dr. ARTHUR TRACY CABOT of Boston read this paper. He termed his paper a study in pathological physiology. He urged operating surgeons to observe more closely the behavior of organs under the varying conditions which they themselves imposed. By such observations many important contributions to pathological physiology have been made, and doubtless many others were under our eyes waiting to be noted. The kidneys offered an especially favorable field for this sort of study, and he offered some observations on their functions as relieved by pressure. An increase of internal pressure in the kidneys was usually brought about by some obstructive lesion in the outer urinary passages. When this obstruction came about gradually, the kidneys adapted themselves to the increasing pressure. The urine gradually drops in specific gravity, but, at the same time, increased proportionately in quantity. The elimination of solids diminished slowly, but a point was reached where the dilute urine did not succeed in carrying off the waste products in sufficient amount, and characteristic symptoms of systemic poisoning manifested themselves. This series of events was mainly due to a gradually developing interstitial nephritis Some thought that this interstitial change in the kidney was part of a general sclerotic change in the organs and blood vessels of the body, the enlargement of the prostate was only another manifestation of the general condition. He thought that the condition of the kidney was secondary to the enlargement of the prostate, and due directly to the obstruction to the flow of urine. When the bladder was tensely filled there was an increase of tension in the kidney. Experimental investigation of the influence of the obstruction in the prostate upon the kidney was not easy on account of the difficulty of reproducing in an animal the gradually forming obstruction which educates the kidney little by little to perform its functions under increased tension. He had treated a certain proportion of these cases by the installment of an in-lying catheter. This method gave an unusual opportunity for studying the effect of the simple relief of tension. The introduction of drainage by a catheter inflicted no trauma and produced no decided change in the condition beyond that incident to emptying the bladder. Once empty, the viscus is kept drained, and the ureters and pelves of the kidneys emptied themselves, and afterward remained empty. If the relief of tension in the urinary passages was followed by a resumption or great improvement of function on the part of the kidneys we were justified in supposing that the previous interference with the function of these organs was in large part due to the tension, and so due to the obstruction which caused it. Hence he believed the prostatic condition was in a large degree responsible for changes in the kidneys. The pyelonephritis, which was almost invariably found in the post-mortem examination of patients, who have died of uræmia, was consequent upon obstructive conditions in the prostate. The microorganisms that caused this inflammation were usually introduced by the use of instruments employed for the relief of retention. Nearly every bladder habitually emptied by a catheter was sooner or later infected. The valvular opening of the ureter prevented the extension of the inflammation backward to the kidney in the majority of cases. His method was to put a soft catheter into the bladder, and to so arrange it that it drew the urine steadily without irritating the vesical walls. It was fastened so that it stayed in place, and was watched closely so that it should never stop running more than a few minutes at a time. He took for granted that a patient with obstructive disease of the prostate and dilated bladder might be regarded as having some degree of interstitial nephritis if the urine was abundant and of low specific gravity. If such a patient suffered from anorexia, nausea and dry mouth, with or without psychical disturbance, these were looked upon as symptoms of uræmia due to this interstitial nephritis. If the patient had high fever and the urine contained pus, it might be regarded as probable that he had pyelonephritis. This supposition was strengthened if one or both kidney were found to be tender or enlarged. In such cases efficient drainage resulted in very great amelioration or even total disappearance of febrile and uræmic symptoms. He favored diuresis by the administration of large quantities of water. In some cases the change from constant drainage to intermittent catheterization was accompanied by a return of inflammatory symptoms. In such cases continuous drainage must be persisted in until a time had been reached when it could be safely dispensed with. The most reasonable explanation of this acquired safety for kidneys that had shown a tendency to retroinfection was that the ureters gradually contracted somewhat, and the bladder being no longer stretched recovers its muscular tone and restores valvular condition at the ureteric orifices. The first effect on the urinary secretion produced by drainage was a considerable increase in the amount of urine. This increase was shown by the fact that the specific gravity did not diminish in proportion as the amount of urine increased, and, also, by the improvement in the patient's condition. After this first accession of polyuria the quantity of urine gradually diminished, while the specific gravity rose. He had continued catheter drainage until all symptoms disappeared and the urine had returned to a tolerably normal condition. If on attempting to dispense with the drainage there was any return of fever and diminution of quantity of urine the drainage was at once restored and continued not only until all symptoms of trouble subsided, but for a considerable time longer. The change might be made very gradually by stopping the flow through the catheter for a gradually lengthening period of time each day; then it might be left out for two or three hours in the morning, and reintroduced and fastened. As safety permitted, the intervals might be gradually lengthened until a return was finally made to catheter life. He did not wish to be understood as regarding this method of treating prostatic cases as in any way superseding other operative procedures. It was applicable to very old or very broken patients who were not fit subjects for operation, or for those who would not consent to surgical operation. It was also of great use in preparing patients for more serious operation.

Dr. EUGENE FULLER of New York referred to the element of back pressure of infected urine causing a bacterial nephritis, which could be relieved by this method of drainage.

**Officers Elected.**—*President*, Dr. Edwin C. Burnett of St. Louis, Mo.; *First Vice-President*, Dr. F. Tilden Brown of New York; *Secretary*, Dr. John Van der Poel of New York. Next place of meeting, St. Louis, Mo.

---

## AMERICAN DERMATOLOGICAL ASSOCIATION.

*Twenty-seventh Annual Meeting, Held at Washington, D. C., May 12, 13, and 14, 1903.*

**Special Report to the Medical Record.**

*Tuesday, May 12—First Day.*

DR. JOHN T. BOWEN OF BOSTON, PRESIDENT.

**Methods of Teaching Dermatology.**—This was the titie of the President's address. He stated that the didactic lecture, the clinical demonstration and the recitation all had their place in the teaching of dermatology. How much time should be accorded to each was a question about which there might be much difference of opinion, and it would often have to be decided according to the resources of the department. He laid the most stress, however, upon the advantage of the method of teaching

small sections of students from the patient or model, and he believed that in the further development of that system lay most hope of improvement. The method required a large amount of material and a large force of instructors. With the development of section work instruction naturally became more complicated, and more time was demanded of the instructors, so that the best teachers of the future would be obliged, perhaps, to sacrifice some of their private work. In the ideal dermatological department of the future it was to be hoped that the endowment would be sufficient to attract men of ability and enthusiasm to the chair, who would consider research and the teaching of their specialty their chief ends, and who would be willing and able to subordinate their private practice to their vocation as teachers.

**A Case of Unkown Infection of the Skin: Possibly Glanders.**—Dr. J. A. FORDYCE of New York presented this communication. The patient was a man fifty-two years old, a native of Holland. His occupation was that of a cigarmaker. He was a very moderate drinker, but smoked heavily. Denied all venereal diseases. Five years ago he suffered from malaria, and three years later from grippe and pneumonia; since then he had a slight cough at times, and had lost some weight. He did not own a horse, nor had he handled horses recently, but he sometimes waited in a stable near the cigar factory if he arrived before the factory opened. He was admitted to the hospital March 11, 1903. Three weeks previous to that date, while removing ashes from the stove, he received a small scratch on the ring-finger of the right hand. The wound became very painful, and within a few days developed into a running sore. A few days later lesions developed on the upper lip, the right side of the mouth, and on the head. When he entered the hospital he complained of weakness, chilly sensations, nervousness, headache, and anorexia. The initial lesion on the ring-finger appeared as a deep, circular, fairly clean-cut ulcer, about the size of a cherry, without reddening of the surrounding skin or any evidence of cellulitis. It discharged a moderate amount of yellowish purulent material. There was a raised, irregular, confluent erosion of the skin of the upper lip, extending to the angle of the mouth and outward to the cheek for a distance of one inch. In the parietal and occipital regions of the scalp there were four large circular patches, one inch in diameter, with raised flat bases of dark brown color. Subsequently similar lesions appeared in the nose, mouth and throat, as well as on the scrotum and thigh, and death occurred on March 19, four weeks after the original infection. The autopsy, which was made by a coroner's physician, did not reveal any definite lesion to account for the man's death. The bacteriological findings were unsatisfactory, a growth of staphylococcus aureus only being obtained on the various media employed. Inoculations of guinea-pigs failed to give the characteristic reaction which was met with in glanders. Sections of the skin from the primary lesion and from secondary vesicopustules showed the presence of an acute exudative inflammation, with evidence of hæmolysis. Enormous numbers of staphylococci were present in the tissues. The infection undoubtedly occurred on the finger, and rapidly spread by autoinoculation to other parts of the skin and the mucous membranes. It differed in its type from all the forms of infection produced by the staphylococcus or streptococcus. The negative results of the histological and bacteriological investigations left the cause of the process in doubt.

Dr. HENRY W. STELWAGON of Philadelphia said the case appeared to him to be an example of one of those infections following vaccination or inoculation from an animal source.

The President, Dr. BOWEN, thought the case bore a great resemblance to the acute form of pemphigus described by the French, occurring particularly in butchers and those who had to do with animal products.

Dr. FORDYCE, in closing, said the case did not suggest a vaccination eruption. The lesions were very rapidly autoinoculable.

**Recent Contributions to Our Knowledge of the Hysterical Neuroses of the Skin.**—Dr. A. VAN HARLINGEN of Philadelphia said that in a former paper, read before this association in 1897, he reported several cases of erythematous eruptions in hysterical persons, which led to excoriations, or perhaps what might be called superficial gangrene. In a subsequent paper he attempted to collect and classify the various skin affections which had been reported as connected in some intimate manner with the pathology of hysteria. Although most of the hysterical neuroses of the skin were related to each other in their nature, yet it seemed more convenient to regard them as distinct, and record them in connection with their dominant feature. Most hysterical skin affections appeared, at least at first, to be vasomotor in character. This fact had been noted by Bettmann, Perrin, and other writers on the subject. Cases of hysterical gangrene showed certain characteristics common to all. The great majority—in fact, nearly all of the cases—occurred in young females showing signs of hysteria, usually of a mild type. The affection frequently developed after some slight accident, a burn or some injury from a corrosive substance, a cut or a puncture. The first eruption commonly occurred at or in the immediate neighborhood of the injury, with considerable sensory irritation. A similar irritation usually introduced subsequent outbreaks. Sometimes the prodromata of gangrene were entirely absent; at other times the gangrene developed from an urticaria or erythema, or more frequently from pemphigoid blebs. Occasionally, a zosteriform eruption was the first symptom. When gangrene was established, the separation of the eschar often left an intractable ulcer terminating in a keloidal scar. While the extremities were the favorite sites of hysterical gangrene, the face and mammary region and other localities were sometimes involved, such as the external aural cavity and the mucous membranes. The question of self-infliction was of great importance in the study of these cases. In a few instances this had been verified and was traced to the usual causes of a desire to excite sympathy, to escape disagreeable tasks, etc., but a careful investigation into other causes failed to show the use of external applications.

**Recurrent Bullous Dermatitis in an Hysterical Subject.**—By Dr. CHARLES J. WHITE of Boston. The patient was an American woman, twenty-three years old. She was distinctly hysterical and of a markedly neurotic and tuberculous parentage. During the past three years she had been the subject of a left-sided, recurrent, grouped, bullous dermatitis, which each year had attacked one part of the body, and had, by repeated outbreaks, gradually advanced its position, each attack lasting about a week and leaving no mark behind. Dr. White said he regarded the case as an example of a rather extraordinary hysterical dermatosis. He did not see how that diagnosis could be avoided, for it seemed to him impossible to regard these one-sided, periodical, long-continued, progressive bullous outbreaks as due to the ingestion of drugs or to the infliction of self injuries, and he knew of no cutaneous disease with such characteristics, outside of the mysterious dermatoses which he had learned to associate with hysteria. We could not place such an unusual group of symptoms under any of the well-recognized forms of disease, but must remain content to style it simply a cutaneous manifestation of hysteria.

Dr. E. B. BRONSON of New York said that in studying these cases we should always bear in mind that in many hysterical patients there was a peculiar vulnerability or sensitiveness of the skin which was absent in the normal individual. There was no doubt that in many of these cases of dermatitis in hysterical subjects an element of deceit was present, but at the same time it took very slight provocation to produce very surprising effects.

Dr. THOMAS C. GILCRIST of Baltimore said we were too apt to apply the term "neurotic" to an eruption that we could not classify or the cause of which we could not recognize.

Dr. F. J. SHEPHERD of Montreal said he had so frequently detected the practice of self-infliction in these cases that he was skeptical about the spontaneous origin of these gangrenous or bullous lesions. He agreed with Dr. Bronson, however, that there was a peculiar vulnerability of the skin of these patients.

Dr. WILLIAM A. PUSEY of Chicago said he was quite convinced that in certain cases of so-called hysteria we might get dermatoses that were not due to external irritation, but were dependent upon the hysterical condition.

Dr. JAMES C. WHITE of Boston said he thought there was no doubt that even these deep-seated lesions of the skin, which we were prone to look upon as evidences of malingering, might occur spontaneously.

Dr. VAN HARLINGEN said he had arrived at the conclusion that there were certain cases in which the eruption was the result of some internal cause and was not produced by the patient. All these cases belonged to the class of vasomotor disturbances, which embraced dermographism, erythema, urticaria, bullous eruptions, and hemorrhages from the skin.

**Sarcomatosis Cutis.**—Dr. G. W. WENDE of Buffalo reported this case. The patient was a colored woman, thirty-eight years old. The disease, resulting from an injury, made its appearance two years before her death, in the form of tubercles accompanied by marked pigmentation, and creating violent and persistent pain. One year later, when the lesions had attained a certain size, they broke down, and this was followed by suppuration, exuberant granulations and free discharges. Microscopically, the skin tumors consisted of a round-cell infiltration, with scanty intercellular stroma. These formed nodules, chiefly in the hypoderm. The cells varied considerably in size. The disease hardly fell among those described as sarcomata, but should rather be classified, as Fuldt had suggested, among the granulomata.

**Fragilitas Crinium.**—Dr. GEORGE T. JACKSON of New York reported two such cases. The first was in a young man of twenty-six, a clerk. The hair was thinned over the whole top of the head, and was dry and lustreless. There was no sign of dandruff. The peculiar feature of the case was that there was a patch on the left side of the head, another on the right side and a third over the forehead where the hair was short and curled up close to the scalp. These patches were sharply defined, like those of ringworm. There was no sign of inflammation. Under appropriate treatment the patches disappeared within six months and the hair became normal in appearance. The second case was that of a lawyer, fifty-five years old, whose general health was good. His hair had been growing thin for some years. Four or five weeks ago he noticed, on combing his hair, that it was matted on the back of the head. Examination showed that on the top of the head there were two well-marked, rounded, sharply defined patches, about the size of a silver dollar, in which the hair was short and apparently broken off. On the back of the head there was another patch in which the hair was broken off and curled close to the scalp, presenting an appearance similar to the curly hair of the Negro. There were no signs of inflammation. The microscopical examination, made by Drs. E. Wende of Buffalo, and Mewborn of New York, disclosed no parasites, but showed many hair with evidences of tricorrhexis nodosa.

**An Unusual Case of Tuberculosis Cutis.**—By Drs. T. C. GILCRIST and W. R. STOKES of Baltimore. The case was that of a colored girl who was first seen in 1894. She had cutaneous ulcerative lesions on the face, near the eye, and on the nose. Sections from these lesions showed a fairly large number of apparently organized bodies, *i. e.* they had a definite form, and in some instances showed budding varieties. Most of them were situated in giant cells, but some were not. Tubercle bacilli could not be found in the tissue. Enlarged glands in the neck of the patient were removed, and large numbers of similar bodies were found in them; the majority of these had undergone definite calcareous degeneration. A guinea-pig was first inoculated intraperitoneally, and it died in a month. Small nodules were found in the liver. These nodules contained a large number of bodies similar to those found in the glands and skin lesion of the patient. The bodies were present in necrotic areas in the liver, and there were many commencing pathogenic areas in which no bodies could be found. No tuberculosis was present in the guinea-pig. This experiment showed definitely that these bodies were not inanimate objects; otherwise, we would not get necrotic areas and such multiplication of these bodies. The death of the animal was apparently due to the presence and growth of these bodies. Further extended experiments with glands which were excised from the patient two years later did not lead to entirely definite results. Pathogenic lesions were produced in a dog and a number of guinea-pigs. In the dog, which was killed, bodies similar to those found in the patient were present in the enlarged cervical glands. A mold grew in another case, and on potato a pathogenic streptococci was obtained. Nothing could be grown on any media direct from the lesions. The relapsed lesions five years later were undoubtedly tuberculous, as shown by inoculation into a guinea-pig.

Dr. M. B. HARTZELL of Philadelphia said the case was interesting, but he failed to see how Dr. GILCRIST had proved that it was one of tuberculosis Dr. STELWAGON agreed with Dr. Hartzell.

The President, Dr. BOWEN, said that tissue which could not be differentiated histologically from that of tuberculosis had been shown to exist in so many different conditions that it was possible we had to deal here with a class of bodies which were perhaps degenerated elastic fibers or calcareous deposits.

(To be continued.)

## Therapeutic Hints.

**Milk Flour.**—A process for the manufacture of milk flour has recently been devised by a Swede. The product in its dry form is practically imperishable, and when dissolved in water may be used, it is said, for any purpose for which ordinary milk may be used. The cost of reduction to powder is nominal. —*Medical Times.*

**Diet in Neurasthenia.**—The diet must be regulated with particular attention to the blood-pressure. For high tension, a milk diet is given with massage, warm vapor baths and liquids at meals are prohibited. For low tension, good food, meat, regulated exercise, baths, rest, deep massage, saline injections, and oxygen inhalations are prescribed. —R. ROME.

**Gout in America.**—True gout is only one third-more prevalent in England than in this country. The condition here is very rarely hereditary, as most of the sufferers are afflicted with lead poisoning, or are alcoholics.
—OSLER.

**Incontinence of Urine.—**

℞ Tincture of rhus aromatica.....gtts. xx
S. Three times daily. —*Medical Summary.*

**Chronic Interstitial Nephritis.**—A warm bath twice or thrice a week, followed by alcoholic friction, but not with cold ablutions, then rest in bed for one or two hours. A hot air bath or a sweat bath at 40° C., followed by a dry pack with rest in bed, but not by cold effusions. When there is œdema with no complication of the heart this method is especially useful. Winternitz recommends the sweat-bath for the lower part of the body with the heart covered by an ice-bag. —O. LERCH.

# Medical Items.

**Race Suicide in Turkey.**—Turkey has, says the New York *Tribune*, a race suicide question, despite the provisions which the prophet Mahomet made against that contingency. Fifty years ago the rule among Turks was to marry young and to espouse several wives, and, as a rule, families were correspondingly large. Now all this is changed. Marriages are late, and in the enormous majority of cases are monogamous, while families are becoming small to a degree which has alarmed the government. The Sultan has recently promulgated an iradé on the subject, abolishing much of the expensive display connected with Turkish marriages and condemning present tendencies as threatening to depopulate the empire.

**Surgery in Germany and America.**—*World's Work* for August contains an article by a young American surgeon who has been studying in Germany for the past four years. He describes the difference in the methods of the American and German medical man. The first-named, he says, aims at practical and profitable results from his knowledge, while the other regards the matter almost solely from the standpoint of science. The writer says that in the hospitals, or even in general meeting places, in Germany, they talk nothing but shop, and he has known a group of German doctors to leave their dinner half eaten to visit a case under discussion. They are the worst possible practitioners, for they are interested only in technique. He knew a man who went to a German physician with a pain in his leg. That doctor spent an hour each day for five days studying it, and after that time he knew all there was to know about that pain, but he didn't stop it. In this country we would have treated it and thought no more about it except to congratulate the patient in a few days on getting well. They do not care for the patient. He is only a specimen. The writer heard a doctor say perfectly mechanically that he hoped the patient would die so that he might learn some facts from the autopsy. They call American surgeons copyists. Wherever that charge is true, the writer concludes, it is merely that Americans turn to practical service the theories they study.

**Health Report.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U S. Marine Hospital Service, during the week ended September 5, 1903:

### SOME ASPECTS OF THE OLD AND THE NEW: A PLEA FOR CONSERVATISM IN MEDICINE AND SURGERY.*

BY BEVERLEY ROBINSON, M.D.,
NEW YORK.

I TAKE it that as one grows older and more experienced his views about many things change almost of necessity. In youth most things appear rosy-tinted, and almost every new endeavor brings fresh zest and energy and hopeful trustfulness in the outcome. When time and opportunity have shown that much that seemed fair and promising in the beginning is of much diminished value—or, indeed, no value at all—we gradually lose that abiding faith which welcomes every fresh departure as though it were far superior to what already existed. This scepticism which makes one a little slow to approve and accept is good, and we should all recognize it, provided it doesn't make us so much of a doubting Thomas as to be unwilling to admit new things or await the trial of anything until the proof of its unexceptional or great relative value, is distinctly manifest.

The foregoing is a prelude to much of what I would say. I have no intention to go back far in the history of medicine or surgery to illustrate some thoughts I deem of present interest and moment. I do require to refer to some facts which I and others of my time have observed and noted, and if I find myself in accord with the latter, whose thought, character, and sober judgment I most admire, I shall be well content to have written this article.

During winter before last a prominent practitioner of a neighboring city, Dr. Reginald H. Fitz of Boston, brought to our attention[1] the fact, after careful analysis of numerous surgical operations in a large and well-conducted hospital during a period of ten years, from 1890 to 1900, that many of them could not be justified if either the immediate or remote results were fairly considered. In this category were operations for malignant disease of internal organs, especially of the intestines, stomach, and rectum; operations by anastomosis or excision, where mere experimentation or performance was not justified by that rule of action which would have us only do to others what we should be willing to have done to ourselves, if our reasoning were sound. In this connection Dr. Fitz writes, in my judgment most wisely and forcibly: "Operations are undertaken which are followed by the immediate death of the patient; others prove to be wholly unnecessary; and still others leave the patient in a condition of helpless invalidism, often making life worse than death. Any operation which does not better the condition of the patient must be regarded as a therapeutic error, since the knowledge thus obtained shows that the operation should not have been performed" (p. 699).

Within a brief period, say a few years only, there have been considerably over one hundred recorded operations for cirrhosis of the liver,[2] to make a collateral circulation through new-formed adhesions, and thus obtained benefits denied, perhaps, to medical treatment. A few of these have seemed to be favorable for many months, but it remains to be proven what the precise underlying conditions were which permitted success to this degree.

The surgical mind, until very lately, with scarcely a halt being called by anyone in such position as to lay absolute claim to a hearing, has viewed appendicitis as almost invariably a surgical disease, only marked out for surgical intervention. To Sir Frederic Treves, notably by reason of his conservative conduct in the care of King Edward of England and subsequently, when he announced only a short time since, in a public address, what nature was telling us not to do by putting up barriers to prevent undue interference, belongs the signal honor of showing the many erring ones where true knowledge lies.

Referring to his recent Cavendish lecture, Dr. A. H. Hare[3] writes as follows: "Treves ventures the opinion that the pathology of the disease and its general mortality does not sanction the practice of opening the abdomen in every case of appendicitis as soon as the diagnosis has been established. He does think, however, that immediate operation is demanded in all ultra-acute cases, and he does not think, in spite of all expressions to the contrary, that these cases are difficult to recognize. Operation is required in every case in which there is a reasonable suspicion that suppuration has taken place, but in Treves' opinion the question of operation in other cases may be kept in abeyance for the first few days of the attack, and may usually be left open for decision until the fifth day or after." . . . Further, Dr. Treves lays "stress upon the fact that the great majority of cases of appendicitis recover spontaneously without either an operation or the formation of an abscess; that the ultra-acute cases are actually rare, and that relatively to the whole mass of examples of all degrees suppuration may be said to be uncommon." "These views, as we understand them," writes Dr. Hare, "coincide with those expressed by Dr. Maurice Richardson of Boston, in a paper which he read during the past winter in Philadelphia, and as Dr. Richardson's experience has been exceedingly rich, the fact that his views and those of Treves agree is particularly interesting."

In a most valuable treatise, lately published, on "Diseases of the Intestines," Hemmeter devotes considerable space to the presentation of the pros and cons of operative intervention in appendicitis. He "speaks in unmistakable terms in support of the clinician's (*i. e.* the conservative) view. He appears to favor operation *only* when signs and symptoms indicate suppuration, and disagreeable clinical phenomena are increasing."[4]

In this same conservative England last winter a very distinguished laryngologist, Sir Felix Semon, pointed out in his special department what a lust for operation existed as regards the throat and nose.[5] The gynecologist of former years is, happily, less

*Read at a meeting of the Practitioners' Society, May 1, 1903.

prone to excise ovaries and appendages when uterine drainage and gauze packing will amply suffice to promote a cure in many instances without risk to life or future health, as shown by a distinguished New York surgeon, viz., Dr. Wm. M. Polk.[6] No longer do we hear much of excision of drum and ossicles in ears irremediably deaf, so far as mere surgical interference is concerned. I mean the cases of chronic dry proliferative catarrh. To those who believe, Beatsons' operation may still be a means of curing incurable cancer by mere surgical methods; to those who excise the prostate where old vesical catarrh defies all known medical methods —in these and a few other extreme instances, mere experimentation, if no very great ultimate success should follow, would seemingly be justified, at least for a time. Not so, however, operations for brain tumors imperfectly located or deep seated, so that the probabilities are that fatal results will follow local interference, and in any event, no good result could follow from it. Not so, instances in which compression of the spinal cord existed in such a way or for such a length of time, that death may immediately follow from a surgical operation and spinal paralysis will probably remain unchanged. When, indeed, the lust for operation extends even to the purely medical man, and when Sir Lauder Brunton descends from his high rôle of scientist and practitioner to advocate excision of thickened valve and orifice in mitral stenosis, the result of chronic endocarditis, where, alas! does the common sense of man seem to be aiming? In a minor degree, for the man with just medical appreciations, the judgment and action of those who would find a cure in decapsulation of the kidney in certain cases of chronic Bright's disease, seem scarcely commendable.

Other examples might be given which would go to prove what to some seems advancement in surgery of our day, is in reality only proof of too great hardiness or of ignorance of the great purposes of this noble art. Let me rather point, even in a very limited measure, to what surgery is doing that is glorious and sure to endure. Wherever deep-seated pus is present in any cavity—abdomen, pelvis, pleura, pericardium, joint, brain—in the vast majority of such cases we turn to the surgeon for help, and usually we have no reason to regret when he considers it right to interfere. So it is, of course, wherever pus is believed or known to be present in muscle, cellular tissue, or bone. Therefore, we wish and ask for surgical doing in abscess of liver, in localized abscess following appendicitis, in perinephritic abscess, in sub-diaphragmatic abscess, in suppuration following pelvic cellulitis or inflamed, degenerated tubes or ovaries. A suppurated joint should be opened and drained, likewise an empyæmic cavity, a purulent pericarditis, a brain abscess, empyæma of the gall-bladder, an acute osteomyelitis with immediate risk of general infection. So should an appendicitis be operated upon, and none too soon when the general symptoms are grave and threatening, and general peritonitis following acute perforation seems very imminent. An immediate operation for a perforating ulcer of the stomach or the intestine, seems equally called for, and will, at times, bring great and rightful renown. No doubt many cases of impacted gallstones should be operated upon very soon and halting, expectant medicine not long endured. Intraabdominal tumors of the nature of cysts or benignant solid tumors should frequently be removed, and often the result to the patient and to the surgeon will be all their sanguine hopes may desire. All this and much more that is brilliant and beneficial and immeasurably good, we assign properly and rightfully to modern surgery. Why then allow it to go into most hazardous ways, and especially where the chances are very great against any real or lasting success being returned. We are prepared to grant the immense triumphs of modern surgery, thanks to asepticism and perfect drainage. We only become sceptical and inclined to criticise and upraid when through the very impunity which skill and opportunity afford, it shows a subservience to these factors, when, with a wider knowledge and appreciation of general laws which govern disease, surgeons would abandon operations which are useless or dangerous, or, perhaps, while involving only slight risk, may be followed sooner or later by consequences more lamentable than the original disturbance of organ or of health from which the patient primarily suffered.

Where does modern practice tend in medicine? She has her great and noble achievements also; likewise she has many drawbacks. The vast armamentarium of new drugs foisted upon us at every turn seems to be a great ill. Amongst them only a limited few are really useful and relatively innocuous. The powerful ones, and especially those so much used amongst the coal-tar derivatives, do great harm unless used with rare good judgment and in small or moderate doses at all times. So often used to control pain, to diminish fever, to abort ailments which may be but the forerunner of mild or severe infection—can't we see and judge how injudicious and wrong may be such use? Why abandon for them, in any event, the use of preparations that have long been known and used, whose power for good is often considerable, whose harmful action, when properly employed, is practically none. In this category, I would include such anti-febricitants, diuretics, and diaphoretics as spirits of Mindererus, sweet spirits of niter and aconite.

Of course, the question may arise, and often does in a given case—should the fever be treated? The answer to this query is different according to circumstances. Long ago, when fever was regarded as an entity, as a very important disease *per se*, it was invariably treated and very actively. Now, that our ideas have changed and we regard fever as a symptom, of very distinct or various causation, the rational answer must be determined by previous and present conditions. It is admitted theoretically, if we could know, reach and suppress the cause of fever, this would be the best way to treat it. But, in the first place, the cause is often obscure or unknown; again, although we know what it is, we cannot eliminate it and forcibly we are led to treat the mere symptom. The fever may be very mild in type, a part of the natural course of the disease, simply indicative that a disturbance of the organism is present. This disturbance will disappear in due time and in the best possible way, ofttimes, if practically we do nothing—at most insist upon a few hygienic rules, and otherwise leave it alone. On other occasions the fever reaches a relatively high degree, and is more or less continuous. To allow it to follow its course without interference, is this wisdom? Usually, we should reply no. Mild antipyretics should be used in moderate doses, and this is done because of the known possible bad effects produced upon living structures by prolonged rise of temperature, either of a functional or organic nature. Whenever the temperature reaches a very high degree, then the indication becomes imperative to treat it, and to treat it vigorously; for in the latter case death itself may be the immediate or remote result of a conduct of pure expectancy. And even though death may not follow, very serious impairment of the functions of nerves and muscles may be

the outcome, which is not only painful and threatening for a while, but may be lasting as to its expression. Finally, we know high and prolonged temperatures are almost inseparably connected with parenchymatous changes both of muscles and nerves, and which lead to, or occasion directly, disability of organs which much time only can remove, and which in the graver instances give rise to permanent morbid changes of organs and tissues. The method of treating the febrile condition, of course, depends largely upon causation. It may be by hydrotherapy, coal tar antipyretics, refrigerants, or cardiac depressants—and that, as Rudyard Kipling says, "is another thing" and one which I shall touch upon only so far as the former means is concerned.

Fever, I have stated, as we now understand it, is occasionally a symptom so threatening, so indicative of imminent danger, that it should be actively combated. And when this is true, no doubt the judicious use of cold water externally applied saves life, and saves it when no other agent familiar to us will. Witness the effects from cold bathing or affusions in thermic fever. But when in an exaggerated way we attempt to use it to control or throttle, as it were, the march of a pronounced pneumonic or typhoid infection, we have gone too far, and we have lost sight of great principles of medicine, long recognized, and of later knowledge which has come to us from the accurate findings of laboratory research. My views about the disadvantages of the cold bath at times in the treatment of typhoid fever are supported, I am pleased to write, by Dr. H. A. Hare.[1] This distinguished writer, in summing up "our treatment of typhoid fever," says wisely, as I believe, "Woe to him that uses drugs or measures when they are not needed, and woe to him that does not use them properly when they are indicated." Empiricism has first made known to us the great utility of cinchona, of arsenic, of coca. As a remedy for the poison of malaria, no one can doubt the efficacy of the former drug; arsenic as a respiratory stimulant and blood restorer at times, and as an important modifier of numerous cutaneous disorders, is unquestionably beneficial; coca, like tea and coffee, stimulates the circulation notably and beneficially in numerous run-down and adynamic conditions, and unquestionably prevents tissue waste when the store house of material we possess should be garnered and saved as far as possible. With the great developments in the field of pharmacy, quinine and cocaine are frequently made to take the place of the extractive virtues of the whole bark or leaf, and many times, as I believe, with serious disadvantages to the patient. Arsenic is used in so many diseases and in such doses continuously that its power for harm clinically has become very great. Opium, that one great remedy of my earlier days in medicine, is now little used comparatively, and in its place morphine has come boldly to the front upon innumerable occasions. Convenient and most useful, no doubt, is the ever ready hypodermic injection; still, it has its woeful drawbacks in habits acquired, almost impossible to control, and in the deterioration of the digestive organs, so essential to wellbeing when they remain active and in good working order. We have fortunately gotten rid of much polypharmacy of former days which was radically bad, but we have also lost sight of many old formulæ which were of very great value. We have added a few drugs to our daily use which were unknown only a short while ago, and which are of decided value, like nitroglycerin and the nitrites, salicylic acid and the salicylates; but we also make use of innumerable others which probably have only a temporary success and will be shown later to be useless or powerful for harm.

Alas! that many physicians have forgotten in practice the wise counsels of the "Hippocratic Oath." Alas! that many pharmacists fail to adhere to an apothecary's oath of the fourteenth century, which is as follows: "I swear not to malign any of my former masters, physicians, pharmacists or others, whoever they may be; to uphold, as far as in me lies, the honor, glory, ornament, and majesty of medicine; not to disclose to idiots and ingrates their secrets and mysteries; to do nothing rashly, without the counsel of physicians or in the hope of gain; to disown and to avoid like the plague the disreputable and entirely pernicious methods of practice now followed by charlatans, empirics, and dabblers in alchemy, to the great disgrace of the magistrates who tolerate them. May the Lord prosper me as I observe these conditions." (*New York Medical Journal*, November 22, 1902, p. 924.)

It was formerly a well-established dictum—in fact, it is an aphorism almost as old as medicine itself—to keep the bowels sweet and fluent. No doubt the useful effects were shown in aborting inflammation, arresting and diminishing fever or destroying intestinal fermentation. The old-timed castor-oil plant did this, as no other plant has ever done, in my judgment, before or since.

Nowadays, we recur constantly to all known antiseptics, such as salol, naphthalin, bichloride of mercury, carbolic acid, etc., and frequently with small or poor results. It is true that a few so-called disinfectant agents are useful in some instances, and these viz., creosote, salts of bismuth, and the mineral acids, I have mentioned elsewhere. When they are beneficial, I believe their utility is probably to be attributed more to other action than that of a pure antiseptic. Creosote quiets and soothes catarrhal conditions of mucous membrane through elimination, bismuth coats the bowels with a non-irritating, styptic, insoluble powder. The mineral acids supplement frequently an insufficient supply in the stomach, owing to impaired action or diseased changes of gastric tubules. As Goodhart[2] says, however, we fail to understand the facts brought to our attention, when we accuse stomach or bowels too readily of becoming morbidly susceptible to their own products. If it were so, how is it we are not more inimical to high-flavored game and mity cheese? If it were so, would not the course of many on earth be much shortened? Even the most favored colon, as Goodhart states, cannot be prevailed upon to distil eau de cologne. Again the nervous element may not be ignored, especially amongst worried, care-worn, impoverished ones. And without due consideration for, and attention to this factor in so many enlargements, displacements, functional and organic changes of stomach, bowels, and other abdominal viscera—we may have little hope from purgatives or antiseptics—not to speak of the broad domain of modern operative surgery.

Antitoxin in diphtheria; getting rid of anopheles as a prophylaxis of malaria; suppression of the variety of mosquito (stegomyia), which is the carrier of the contagium of yellow fever: these are great additions to our knowledge, the results of which are only partly realized as yet, and the ultimate outcome of which will be of inestimable value to the race. Therefore, it is that we are sanguine, very much so indeed, when and where we have to do with the solid workers, the keen and laborious searchers after truth. But where we become and are of a doubting, chagrined frame of mind, is upon the many occasions, where we run up against shallow ideas and small work, which

characterize those who are in the field for ephemeral praise and mere pecuniary success, and whose "borrowing dulls the edge of husbandry" in the biggest, broadest sense.

The work done by those faithful and true men who are trying to ameliorate in every rational way the care and treatment of patients suffering from pulmonary tuberculosis, is surely much to be commended, for it is praiseworthy and beneficent. No one can doubt, by building properly, sanatoria in suitable country localities, that great good shall be accomplished. No one can fail to see that by insistence upon the importance of limiting the number of consumptives, by giving to them and to all a healthy supply of food, whether as milk or meat, beneficent results will be effected. In the same way, we cordially endorse proper rules governing expectoration in all places of public or private resort; we support heartily the improvement in our tenements by giving more air, more sunlight, improved plumbing, less crowding, inasmuch as all of these reforms tend to lessen the number of the tuberculous, and make for the cure of those already affected. Further, to insist upon proper precautions in the home to prevent the well ones from taking the seeds of this disease, is work which properly belongs to the sanitarian, to the physician, to every man who wishes to benefit and uplift the race. As to purely medical care, in the sense of prescribing proper régime and suitable remedies for those threatened or already diseased, that too is good work and worth accomplishing in a thoroughly scientific and honest way. Let us not be unmindful, however, of commendable work done in the past and by men who stood deservedly high amongst us not very long ago. The late Prof. Austin Flint, a most distinguished observer, showed conclusively by the analysis of six hundred and seventy cases of pulmonary tuberculosis, done in a very careful, judicious, and erudite manner, that a proportion of one to fifteen of these cases are self-limited as to the duration of their disease, and will surely recover, if only a very moderate attention is paid to ordinary rules of living, and even amongst the impoverished and scarcely well-to-do of our land, in very numerous instances. Professor Flint also showed that a nearly similar proportion of cases would secure in like conditions a suppression of all symptoms for periods of time, of longer or shorter duration. Thus, the disease itself, even though the physical condition might remain, became absolutely quiescent, so far as outward manifestations went—such as cough, sweats, loss of flesh and strength, expectoration, fever. To those, therefore, who would claim for every new drug and every new treatment advantages and an efficacy which appear at first as brilliant in their curative action, we would turn to Flint to have his wisdom guide and direct us, rather than to restricted knowledge which accounts for too much with agents imperfectly known and understood. Self-limitation exists also in many other diseases, especially those of acute and infectious type—and just as frequently to-day as hundreds of years ago, the eruptive fevers go through well-determined stages of incubation, development, march, and termination without being influenced very materially, or shortened appreciably, or at all, as to their duration by any specific or known treatment. The law governing in many particulars, the self-limitation of disease goes back to Jacob Bigelow, who first insisted upon it in 1835.[10] It was to the elder Flint,[11] however, that belongs properly, in my judgment, the extension of this law with special emphasis to cases of phthisis. Flint writes as follows, and it is to these wise remarks we now would direct especial attention: "A host of diseases have been shown to be self-limited. All the essential fevers, inclusive of pneumonia, and many acute inflammations, are, as the term has been defined, self-limited diseases. . . . If the term be used in a sense embracing different degrees of that attribute of disease which renders it independent of treatment, as regards course and termination, most diseases are more or less self-limited; and it is of interest to inquire, in different cases of the same disease, how far the course and termination may be due to self-limitation."

On the other hand, we believe and we think we know to-day that by good ventilation, rest, liquid diet, good nursing, and good hygiene, as regards cleanliness and surroundings and proper disinfection, we neutralize, perhaps, in a measure the virulence of disease in many instances, and prevent complications which are the inevitable result of lack of attention and ignorance. As to climate, and its influence as a curative agent in the treatment of phthisis, a few words here may not be amiss. Flint writes that more or less power for good is due to it, and while self-limitation doubtless played a part in the result, it certainly cannot account for it to the exclusion of climatic effect. This result relates to different climates taken collectively. "If it be sought to determine the comparative advantages of particular climates, we have to deal with a complex problem." . . . "Let it suffice to say that the selection of a place of resort is to be governed by the circumstances proper to each case, and not by any rule applicable alike to all cases. My object in alluding to climate has been simply to illustrate the bearing of self-limitation on the conclusions drawn from clinical studies respecting climatic treatment; and the remarks which have been made are applicable to other hygienic measures, and to different kinds of medication. An important point in clinical studies with reference to all these should be to take cognizance of the relative agency of self-limitation as a factor or co-worker in determining the favorable course of the disease." . . . "Bigelow, when he distinguished certain diseases as self-limited, probably had but a faint apprehension of the scope of this well-chosen term. The boundaries of its fullest extension are yet to be ascertained. Much knowledge of the natural history of diseases still remains to be acquired."

Thanks to the great advances made in nursing in our day, we physicians can usually have our intelligent advice and treatment of patients carried out faithfully and appreciatively, if we have constantly the courage to insist upon what is best for the well-being of our patients and for our own moral self-respect. Whilst, however, we find a very great improvement in mere knowledge of duties on the part of our nurses to those of a decade or two since, I am not quite sure that their realization of the doctrine of self-sacrifice and devotion has continuously improved. I am also firmly convinced that more than one subject they are taught at some length in the schools had better be let alone. This acquired smattering of anatomy, physiology, and therapeutics is often a practical detriment in their rôle of good nurse. They are tempted with their imperfect knowledge to give counsel or direct at times, when they should seek only to comfort and serve.

The germ theory of disease and its enormous and fruitful outcome have been most useful in the promotion of human health and longevity. On the other hand, it is proven that all germs are not destroyers; some are protectors, some are inoffensive. The mere discovery of a germ doesn't prove necessarily of great value, even if it be proven to be the

cause of disease, unless with its life history we reach the means of destroying it or neutralizing any power for evil it may possess. If it be merely a consequence of certain evils; if, in a sense, it be the formed scavenger in disease, its discovery should merely mean that we should endeavor to find out why it is there; if for bad, to get at and root out primary bad conditions; if for good, then hail its advent with satisfaction until we discover the means of avoiding its almost necessary presence, when without, things might go from bad to worse. Moreover, whilst very many acute and some chronic diseases are now recognized to be of microbic origin, others there are about which the microbic origin is still unproven; and in this category we are still forced to place two of those which have threatened and still threaten the human race, viz., smallpox[13] and syphilis (Virchow). Against one of these, fortunately, we have in Jenner's great discovery, vaccination, when generally and successfully used, an almost sure means to combat its growth and extension. Against the other, wiser, and improved legislation can alone lead to its complete suppression, whilst medicine, even the so-called specific, mercury, can but be greatly helpful in numerous instances in which it is present, without being invariably an absolutely curative agent in every instance.

In the doctrine of immunity as it is now being investigated by the great scientists of our own and foreign countries, we discover a hopeful outlook and wider scope for increasing and more accurate knowledge to penetrate the hidden mysteries of many things, the ultimate outcome of which, striving and research, will be enormously valuable to future generations.

To many who speak of immunity, I fear sometimes that what is understood by it is not clearly apprehended. No doubt, it suggests to different minds different ideas. There is immunity by taking a disease such as smallpox, measles, scarlet fever, etc., and there is another form of immunity that might be termed natural immunity from the fact that a person has inherited a resistance against special diseases. Certain people do not take certain diseases under any circumstances. They are born with a constitution which resists it. Again, there are cases in which immunity is a variable quantity, in which it is dependent upon the condition of the body relative to vigor, etc. All the curious manifestations suggest a changeable condition of the molecules which make up the vital structures. Immunity certainly is nothing but a molecular condition of the living material out of which our bodies are constructed. When immunity is acquired from having had a disease, the poisons which the system is bathed in during the progress of the disease set up some molecular disturbances which renders the body resistant to further intoxication.[13]

In the question of immunity there are two recognized ideas at present—first, immunity against bacteria; second, immunity against their poisons or toxins.

There are also two theories which prevail in regard to immunity—first, the phagocytic theory; second, the old humoral theory.

Metchnikoff,[14] the great advocate of the former theory, states: "Under conditions in which the cells retain their vitality, it is phagocytosis which is eminent; when they suffer widespread destruction, the serum becomes bactericidal, and the microbes are disposed of not intracellularly but extracellularly. Herein we see some light upon the apparent contradictions between immunity and the bactericidal virtues of the juices." . . . Generally speaking, immunity to microbes can be secured independently of immunity to toxins, the former being unfortunately much the easier achievement."

In studying natural immunity it is also shown that the serum of immune animals is often an excellent culture medium, thus showing that there is a powerful mechanism in the economy other than that contained in their juices to combat microbic infection. It has been shown in cholera and typhoid fever that bodies immunized by bacteria are poisoned by the toxins of the same bacteria. The subject of agglutination is still an undetermined question. The agglutinating and immune substance which were thought to be one and the same are now known to be distinct. The study of precipitins in the blood bids fair to become of great medicolegal interest.[15]

In speaking on immunity, Prof. Wm. H. Welch says: (*Lancet*, October 11, 1902, p. 983.) "These researches, which have already led to the saving of thousands of human lives and will lead to the saving of untold thousands more, have been carried on by the experimental method and can be conducted in no other way. This method is as essential for the advancement of medical science as for that of any of the natural or physical sciences. To restrict unnecessarily and unjustifiably its use is nothing short of a crime against humanity."

Chemical and bacteriological research and the general use of the microscope have made additions to our knowledge of untold value already. Very many practitioners of to-day have been made by these one-sided, and they have abandoned not a little the broad appreciations which enable one to see always the general laws which govern the manifestations of disease, and without which knowledge he is, indeed, but a poor and lame practitioner who attempts its cure. Modern specialism finds a local trouble almost everywhere, and in its effort to right things and make them perfect locally, ignores too much underlyling causes, and in the end frequently produces woeful results. Upon the whole, looking backward, do we regret the past altogether? looking forward, do we consider every new achievement a decided and manifest gain? The answer is not difficult. We feel deeply and intensely that we should hail what is new with interest and moderate enthusiasm at first, and not adopt it too soon as the beacon light to be followed until we have fully tested wherein it is good and wherein it fails. We feel with equal strength and earnestness that we should not abandon former lines of thought and the action that proceeded therefrom, simply because they are time-worn. Ideas, like clothing, are not threadbare merely because they have been worn, and if they be of good material and good make, they last at least for a time, and are still valuable. Ideas, like gold and precious jewels, sometimes, frequently perhaps, never lose their intrinsic and great value. We may change and modify and reset, but they remain all the same in reality, and to the man who is appreciative and who knows, they prove to him that he is wealthy when others are poor indeed. The burden of this article and its summing up is to make one—all of us—conservative—conservative in the best sense, viz., "Prove all things; hold fast that which is good."

## ABNORMAL FREQUENCY OF URINATION TREATED WITH EPIDURAL INJECTIONS.

BY FERD. C. VALENTINE, M.D.,
AND
TERRY M. TOWNSEND, M.D.,
NEW YORK.

IT is a pleasant duty that obliges recognition of the kind encouragement and aid provided by Dr. E. C. Dent, Medical Superintendent of the magnificent Manhattan Hospital West, without which even these preliminary studies would have been impossible. The senior writer of this paper submitted to Dr. Dent the details of the procedure, which he had learned from its author, Fernand Cathelin, at the Hôpital Necker, Paris, in 1902. After a thorough personal investigation of the innocuousness of the little operation, done for demonstration in about twenty-five cases, and observing the results, Dr. Dent gave his consent to a systematic test of the treatment in the great institution which he so ably and scientifically conducts.

If, therefore, permanent benefit accrues to those suffering from the obstinate and distressing condition, the credit therefor is due largely to Dr. E. C. Dent and his hospital.

Full appreciation is also due Dr. Dent for assigning two of his staff, Drs. A. C. Delacroix and A. E. Hutchinson, to assist in these investigations. The assiduity and enthusiasm with which these junior colleagues did and are doing their work in this matter show the Superintendent's wisdom in selecting them for the purpose. In view of the preceding, it is clear that all credit for priority in America in the epidural treatment of urinary disturbances of urination belongs to Dr. Dent and his staff.

Ordinarily it would be premature to report on but eight cases, under observation less than three months. But the results in these eight are so encouraging, that it seems well to lay them before the profession with a view to having the matter tested by others. About twenty-five other cases were treated besides those noted here, but as these were removed by their relatives or discharged before any results beyond improvement could be recorded, they are not embodied in this report. In all the twenty-five patients as in the eight reported below, the injections were followed by no untoward results, and the frequency with which their beds and clothing were wet, or the abnormal frequency of voluntary urination, was either reduced or entirely checked, at least for the time being.

Precise records of the cases submitted below were begun on May 9, 1903, so far as concerns their enuresis or diurnal incontinence or abnormal frequency of voluntary urination. In this the painstaking detailed records of the hospital proved inexpressibly valuable. It is from this extraordinary wealth of material that the following abstracts have been made. On first examination of these records it was found that the patients affected with enuresis or incontinence, or both, were recorded, as is usual, as "wetters." A request to have the records amplified was met, as are all others for the patient's benefit, by prompt specific orders to the nurses to record (1) the frequency with which patients urinated in bed during sleep; (2) the frequency with which they wet their garments while awake; (3) the frequency with which they urinated voluntarily.

*Synopsis of Cases.*—I.—A. R., Book 47, folio 299. Age 24, single. Uterus and appendages normal. Menstruates every four to six weeks. Urinary organs normal. Urinalysis* (August 9, 1903) negative. No history of injury to any part of body. Children, none. Admitted to hospital July 3, 1896, for imbecility, chronic melancholia, chronic valvular endocarditis. On admission had a history of enuresis; precise record thereof begins May 9, 1903, when she wet her bed, obliging a change of sheets eighteen times during that night. Previous to the first epidural injection she had experienced occasional relief from strychnia (gr. $\frac{1}{60}$ to $\frac{1}{15}$) and the other remedies usually employed for this condition.

The records of her frequency of urination from the first epidural injection are as follows:

May 9, 1903. Frequency of nocturnal urination as above noted. First epidural injection 10 c.c., which was repeated May 16.

May 20, 1903. Since first epidural injection patient urinates in bed ***twice nightly*** instead of eighteen times, as before.

June 20, 1903. Epidural injections have been repeated once a week since May 20. Patient urinates in bed twice and ***awakes to go to urinate voluntarily*** three times nightly. Epidural injection increased to 15 c.c.

July 29, 1903. Epidural injections have been administered once a week, increasing the amount to 25 c.c. Patient wets bed once and goes to toilet once at night.

August 19, 1903. Injections have been suspended for observation since July 29. Patient urinates in bed once at night, and arises to urinate once a night; does not urinate into her garments during the day. Urinates voluntarily on toilet, five times daily. No injection.

II.—M. H., Book 10, folio 235. Age 40, widow. One child, non-instrumental birth. Small incomplete perineal and bilateral cervical laceration. Retroversion. Has not menstruated for over a year. Urine (July 29, 1903): Specific gravity 1010. Acid. Slight trace of albumin. Calcium oxalate crystals. Many squamous epithelia. Few granular casts, bacteria and fungi.—Paranoiac. On admission, April 28, 1903, she wet her garments six times daily and ten times every night. The duration of incontinence could not be learned. Medication had proven unavailing. The records show:

June 16, 1903. The patient wet bedding ten times at night, and urinated into her clothing six times daily. Epidural injection 5 c.c.

Epidural injections were increased to 7.5, 10, 15, 20, 25 c.c. respectively on June 23, 30, July 7, 13, 20. On July 27 20 c.c., repeated on August 7. Gradual improvement occurred until July 2, 1903, when she urinated into bed occasionally (not every night) and wet her garments once during the day.

July 9, 1903. With an attack of diarrhœa, incontinence recurred. Diurnal and nocturnal frequency could not be noted.

July 25, 1903. Wet bedding three times; although she was taken to the toilet regularly, did not respond at those times.

*The urinalyses noted in this paper were made by Dr. Adolf Myers, Pathologist of the Manhattan State Hospital West.

July 29, 1903. Wet and soiled bedding twice.

July 31. 1903. Diarrhœa ceased. Has not wet bedding or clothing since 29th. No injection *experimenti causa*.

August 12, 1903. Did not wet bedding or clothing since July 29 (two weeks). Epidural injection 15 c.c., to ascertain whether after the relief obtained it would in this case provoke any change.

III.—I.B.R., Book 199, folio 9946. Age 26, married, one child, born October, 1902: non-instrumental labor. Perineal and cervical lacerations. Retroflexed uterus. Urinalysis May 11, 1903: Acid, Specific gravity 1022. Faint trace of albumin. Squamous epithelia. Amorphous urates. Has received no injury to any part of body. Admitted January 30, 1903, for acute melancholia (dementia præcox). At that time she was reported as "wet and filthy," which condition continued and was again specifically noted April 29, 1903, "wets bedding several times daily." On June 20 she is recorded more in detail as wetting clothing and bed every ten or fifteen minutes day and night. She has received urotropin gr.v t.i.d., which was not followed by any change in the frequency of involuntary urination.

June 27, 1903. The condition as described above continues. Epidural injection 5 c.c.

July 1, 1903. No perceptible improvement observed. Epidural injection 10 c.c.

July 7, 1903. Wets bedding twice nightly and clothing two or three times daily. No injection; requested close observation.

July 27, 1903. Patient goes to toilet voluntarily to urinate twice at night and six times during the day. Does not urinate into bed or clothing, but continues to defecate into both, as before. Epidural injection 20 c.c.

August 12, 1903. A relapse is recorded as follows: Urinated into bed once nightly until the 8th: thence to date twice every night. Does not wet clothing at all during the day, but voluntarily urinates on toilet from two to six times. Epidural injection 25 c.c.

IV.—A. F., Book 10, folio 366. Age 18. Genitalia normal. Nullipara. No history of injury. Had an apoplectic (epileptic?) seizure when fourteen years of age. Admitted May 13, 1903, for epileptic dementia, when daily and nocturnal incontinence were recorded; how long it had existed before admission, was not ascertainable. She urinates involuntarily with each convulsion, and at least twice into bed every night.

July 15, 1903. Frequency of involuntary urinations as above noted. Epidural injection 10 c.c.

July 23, 1903. Urinated in bed once at night, but has not wet clothing. Epidural injection 15 c.c.

July 29, 1903. Has not wet clothing since first epidural injection Epidural injection 15 c.c.

August 12, 1903. On August 3 had a convulsion, during which she urinated into her clothing. Since then she has not urinated in bed or into her clothing. Urinates voluntarily on toilet four to six times every twenty-four hours. No epidural injection.

V.—M. H., Book 10, folio 333. Age 37, widow, nine children; no instrumental labor. Incomplete perineal laceration; bilateral cervical laceration, hypertrophied cervix. Menstruates regularly. Dementia præcox. No history or evidence of injury to any part of body. Definite history of previous abnormal urination not obtainable.

July 15, 1903. Urinates into her clothing and bed every ten minutes day and night. Epidural injection 10 c.c.

July 22, 1903. Has not urinated into clothing or bed for one week. Voluntarily urinates on toilet three or four times daily and four times at night. Epidural injection 15 c.c.

July 29, 1903. Has not wet bedding or clothing for two weeks. Goes to toilet three or four times daily; does not urinate at night.

August 5, 1903. Menstruating profusely; impossible to determine whether clothing is wet from menstrual discharge alone or whether urine is mixed therewith.

August 12, 1903. On the 7th, while mentally much disturbed, urinated into clothing once, but urinated voluntarily on toilet twice thereafter on the same day. Epidural injection 10 c.c.

VI.—A. H., Book 79, folio 6,321. Has no friends to furnish information. Sometimes says she is forty-four or forty-nine, or fifty-three years old. Memory poor. On first admission in 1887 she was thirty-two or thirty-six years of age. At second admission in 1899 she was forty. Married. A cicatrix on abdomen shows that an extensive operation was performed, which she says was done for rheumatism at Charity Hospital six years ago (she was at the Manhattan Hospital West six years ago). Genitalia atrophied. Meatus urinarius externus swollen and reddened. Urine July 21, 1903: Acid. Specific gravity 1032. Faint trace of albumin. Considerable pus. Large round squamous epithelia. Bacteria. Amorphous urates.—Scars on right temple and neck, which she attributes to injuries from falling into a coal pile some years ago; this is possible, as she is an alcoholic. Four or five children; she says that none of the labors were instrumental. Admitted 1887 for acute melancholia. Readmitted 1899 for secondary dementia. Has alcoholic and specific history. Record, from June 20, 1887, shows numerous fits, some followed by paralysis of the leg, some by aphasia, some by loss of speech. These sequelæ were transient. The first disturbances in urination recorded are: April 24, 1888, suppression of urine. May 1, 1888, scantiness of urine. April 20, 1899, incontinence. August 4, 1900, dysuria. May 11, 1903, nocturnal incontinence. Does not wet garments, but goes to toilet every hour or two when awake. May 16, 1903, epidural injection 10 c.c.

May 23, 1903. Urinated into bed once nightly. Diurnal frequency unchanged. Epidural injection 15 c.c.

May 30, 1903. Condition same. Epidural injection 20 c.c.

June 7, 1903. Condition same. Epidural injection 20 c.c.

June 13, 1903. Condition same. Epidural injection 20 c.c.

June 20, 1903. Does not urinate into bed every night, but did last night and the night before. Epidural injection 25 c.c.

June 27, 1903. Has not wet bed past four nights; urinates on toilet five times daily. Epidural injection 25 c.c.

July 1, 1903. Has not urinated into bed or clothing. Epidural injection 25 c.c.

July 8, 1903. Urinated voluntarily on toilet four times daily. No nocturnal urinations. No epidural injection.

July 19, 1903. Same record as on 8th. Has not urinated into bed since June 22. No epidural injection.

August 12, 1903. Urination continues normal. No epidural injection.

VII.—S. E., Book 9, folio 335. Age 29. Six months before admission both ovaries, and a greater part of labia minora were removed and ventro-suspension uteri probably performed. Urine, April 15, 1903: Acid. Specific gravity 1011, epithelia, mucus, amorphous urates, calcium oxalate, triple

phosphates.—History of occasional incontinence since May 24, 1902—Cystoscopy, July 22, 1903, showed minute phosphatic concretion at vault of bladder and some areas of inflammation near mouths of ureters (patient had had cystitis in June, which yielded to irrigations with silver nitrate). One child; non-instrumental labor. Diagnosis on admission: Imbecility; acute mania.

The incontinence since May 24, 1902, was exclusively nocturnal. It was not regular, as she wet the bed only occasionally.

July 29, 1903. Epidural injection 10 c.c.

July 31, 1903. Arose to urinate on toilet twice last night; urinated voluntarily four times during day.

August 3, 1903. Same record as July 31. No injection.

August 6, 1903. Went to toilet three times last night and urinated into bed once—the first nocturnal incontinence since July 28. No epidural injection in order to determine whether nocturnal urination was due to a possible recurrence of cystitis.

August 12. 1903. Has not wet bedding since August 5. Epidural injection 15 c.c.

VIII.—L. H. Q., Book 9, folio 140. Age 49. Alcoholic. Married. Atrophied genitalia, cervical and perineal laceration. Menopause established, which she denies. Urinalysis July 21, 1903: Acid. Specific gravity 1010. Slight trace of albumin. Pus. epithelia, bacteria, crystalline and amorphous urates, triple and amorphous phosphates. Has had incontinence, history thereof not ascertainable. Small perforation of hard palate, which she attributes to an injury by artificial denture. Scar on right side of nose near tearduct; says some operation was performed on eye when a child (memory defective). Dr. J. L. Barnes, Visiting Ophthalmologist, performed Bowman's operation for dacryocystitis. Six children, no instrumental labor. Admitted January 10, 1903, with dementia secondary to alcoholism. This patient was not brought for treatment for incontinence, but as she urinated painfully four or five times at night and eight or ten times daily (*i. e.* twelve to fifteen times in twenty-four hours), though not into bed or her clothing. This condition had persisted since January 10, 1903 (five months), to the first epidural injection.

May 16, 1903. Epidural injection 5 c.c.

May 23, 1903. Urinated three times at night and seven times daily. Epidural injection 7.5 c.c.

May 30, 1903. Urinated twice at night and six times daily. Epidural injection 7.5 c.c.

June 6, 1903. Urinates twice at night and five or six times daily. Epidural injection 10 c.c.

June 13, 1903. Frequency unchanged, but urination is painless. Epidural injection 15 c.c.

June 20, 1903. Same record as the preceding. Epidural injection 20 c.c.

June 27, 1903. Record unchanged. Epidural injection 25 c.c.

July 1, 1903. Urinates four or five times during the day; not at all at night. Epidural injection 25 c.c.

July 8, 1903. Same record as last week. No injection.

July 18, 1903. Urination normal. Treatment suspended.

July 20, 1903. Arose to urinate on toilet once last night and five times during the day. No epidural injection.

August 12, 1903. Urination normal. No treatment.

*Résumé of the Cases.*—Omitting all other considerations, the following résumé of these cases may be submitted:

I.—Incontinence first recorded July 3, 1896. Before epidural injections urinated into bed eighteen times at night. After first epidural injection urinated into bed twice at night. After tenth epidural injection urinated into bed once and went to toilet five times daily.

II.—Incontinence first recorded April 28, 1903. Before epidural injections urinated into bed ten times nightly and into her garments six times daily. Improvement was gradual. After tenth epidural injection did not wet bed or clothing.

III.—Incontinence first recorded January 30, 1903, when she was reported as being "wet and filthy." On June 20, 1903, recorded as wetting clothing and bed every ten or fifteen minutes. After fourth epidural injection wet bed twice nightly; did not wet clothing during the day.

IV.—Incontinence first recorded May 13, 1903. Then urinated into bed at least twice every night. After first injection urinated into bed once at night, but did not wet clothing except during a convulsion. After the third epidural injection, urination appeared to have become normal.

V.—Incontinence first recorded July 15, 1903, "every ten minutes day and night." After first epidural injection, diurnal urinations became normal, and nocturnal voluntary four times nightly. After the second epidural injection she ceased to urinate at night. Twenty-two days after first injection, while mentally disturbed, urinated into her clothing twice, but returned to normal micturition on the same day.

VI.—Incontinence first recorded April 29, 1899. More recently urinated into bed once nightly and continued to do so until five epidural injections had been given, then urinated into bed occasionally. After the fifth epidural injection (25 c.c.) ceased to urinate into bed. Had no incontinence thereafter up to present time—fifty-six days after first injection. She received no injection in the nineteen days preceding this report.

VII.—Incontinence first recorded May 24, 1902, as "occasionally nocturnal." Nine days after first epidural injection, urinated into bed once. Fourteen days after first injection, received a second. As this patient had, before receiving injections, only occasional nocturnal incontinence, no conclusions can as yet be drawn from her record.

VIII.—This patient had a history of incontinence previous to her admission. Since five months before the first epidural injection had painful urinations four or five times nightly and eight to ten times daily. After the eighth epidural injection, urination became normal and remained so since (forty-three days at present, August 19, 1903).

*Objections to This Report:* I.—It offers a study of only eight cases. The results in these, however, are sufficiently encouraging to warrant offering them in the hope that others may take up the matter and coöperate in further developing it. These cases, furthermore, are far more valuable than those in private practice, because (*a*) all these patients are insane; not one knew the object of the treatment, therefore no deception, suggestion, or autosuggestion could have had any bearing upon the improvement; and (*b*) all urinations were recorded by nurses detailed for this special purpose, under the supervision of the staff of the hospital, whose records are not at all likely to be colored by enthusiasm.

II.—The histories are not complete as far as concerns abnormalities in urination. It must be remembered that all these patients are defectives, consequently they could not give any reliable

history of their disturbances prior to admission. One of them has no friends or relatives. Those connected with the others either could not be credited with sufficiently close power of observation or were too indifferent to note the details that would be necessary for precise records. Then, again, in an institution of such magnitude, with about 2,400 patients. an overworked Chief and staff, it is remarkable that these patients were at all recorded otherwise than as mere "wetters." Moreover, until these studies were begun, there was no inducement to do more in this special regard.

III.—This preliminary report contains no records of children or male adults affected with abnormalities in urination. They are purposely left out of consideration here, for two reasons: (1) the institution in which the more systematic work could be done has exclusively female patients; (2) in all private cases that have so far been brought to the authors, an inflammatory condition, abnormalities of the urine, a congenital deformity, or a foreign body, presented a direct cause for excessive or involuntary urination. In only one private patient could the effect of epidural injections be observed, and then unsatisfactorily. This is a youth of twenty-one, who had urinated into bed several times at night since his birth. Under epidural injections he became entirely continent, but each time that he was too lazy to go to the closet before retiring he urinated into bed.

*The solution used* in all the cases was a sterilized decinormal salt solution at a temperature of 99 to 100° F., and in the quantities mentioned in each case.

*The instrument* is a syringe of a capacity of 5 c.c. It is provided with tempered steel needles 0.06 long; seven-tenths of a millimeter in caliber, with an eye 3 mm. in size, at the point.

The syringe and its needle is sterilized by boiling, and the needle is passed through an alcohol flame before each injection.

TECHNIQUE OF EPIDURAL INJECTIONS.

*Anatomical Considerations.*—The objects in view can naturally be best studied by carefully refreshing the anatomy and the variations therein of the region under consideration. For the present purpose it will suffice to say that the injections are made into the sacral canal between the periosteum of the vertebræ and the dura mater. The canal is reached through its opening in the sacrum (marked x in figure 1.)

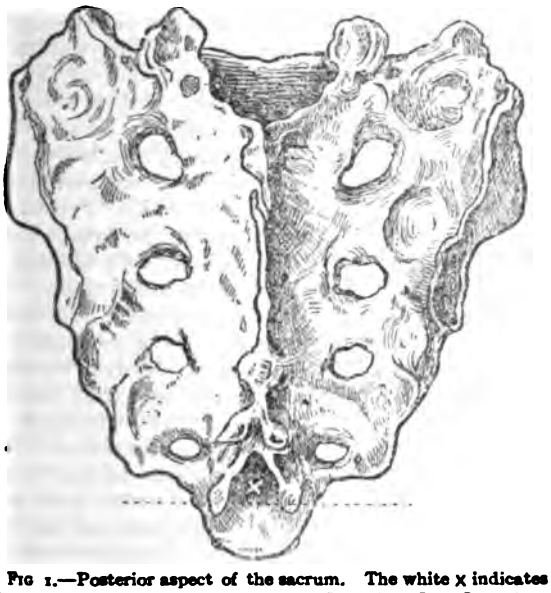

FIG 1.—Posterior aspect of the sacrum. The white x indicates the point to be perforated. (From Cathelin: Les Injections Épidurales.)

The sacral hiatus is not, however, in the line between the nates when the patient lies on his side, as is shown in Figure 2.

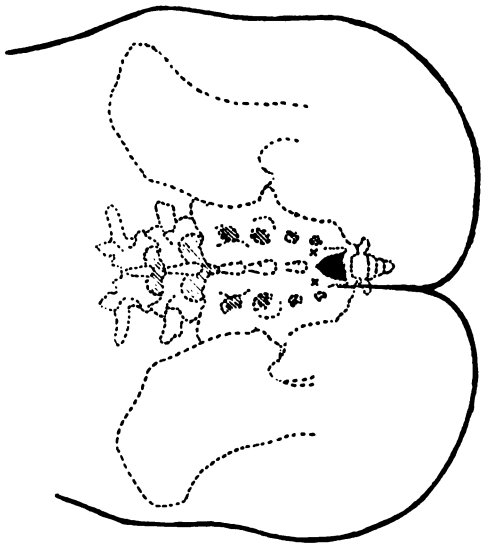

FIG. 2.—Non-concordance of the sacral orifice and the natal crease, when the patient is placed on the left side. (From Cathelin: Les Injections Épidurales.)

*Position of the Patient.*—The patient may be placed on either side, most comfortably on a table sufficiently high to render excessive stooping of the operator unnecessary. Cathelin,* in speaking of epidural injections for other affections than these now under consideration, advises placing the patient on the painful side. When epidural injections are made for disturbances in urination, it is well to place the patient in a species of Sims's position, with the knees drawn as tightly as possible toward the chest and the legs flexed.

*Sterilization of the Region.*—The skin over the sacrum is scrubbed thoroughly with Synol soap, then wiped with sterile pledgets of alcohol, but not dried.

*The operator's hands* are cleansed in the same manner as is the region to be punctured.

*Finding the Point of Puncture.*—The left palm is pressed upon the sterilized skin, with the fingers well extended and held closely together. They are passed down the skin over the sacral spinous processes until the last perceptible one of these is felt under the pulps of the left index and middle fingers. These are then slightly separated and pushed downward until each of them presses an osseous tubercle. The skin is firmly stretched with the same fingers over these tubercles; between them is the space to be punctured.

*The Puncture.*—The needle is taken between the right thumb and middle finger, the tip of the index-finger resting upon the attachment of the needle. So held, at an angle of about 40° to the sacral curve, it is thrust through the space of skin tensely stretched by the left fingers. An instant later the right fingers receive the sensation that is imparted when an instrument is tested by means of tense drum-head. This is produced by the needle's point traversing the posterior-inferior sacral obturating membrane. The shaft of the needle is then depressed about 20° and the left middle fingers raised from the skin, and the left index is pressed upon the point of puncture to steady the needle and the tissues. In this position the needle is cautiously pushed up into the sacral canal. If each step of the technique has been sedulously followed, and no

*Fernand Cathelin: "Les Injections Épidurales." Baillière, Paris, 1903.

gross abnormality exists, the needle can be entirely inserted without touching the periosteum of any part of the sacral canal.

*The Injection.*—The left thumb and index-finger then firmly hold the needle's attachment, while the syringe is attached by the right hand. Nine-tenths of the contents of the syringe are then slowly injected into the sacral canal without moving the needle. Then, still slowly injecting, the needle is gradually withdrawn until its point is just beneath the skin. The last drop or two of the solution are then forced out, forming a little bulla at the point of insertion. If these precautions are carefully observed, there will not be even a slight oozing of blood from the puncture.

*After-treatment.*—Subsequent to withdrawal of the needle, the region is wiped dry with a bit of absorbent cotton, and the site of puncture covered with a little collodion.

*Claims for Epidural Injections, Based upon the Eight Cases Reported.*—Even now the following claims may conservatively be made for this method of treating urinary incontinence, and excessive frequency of urination, when due only to faulty vesical innervation:

1. The operation is not more painful than hypodermatic injection.

2. Generally there are no immediate after-effects. Some patients experience a sense of pressure extending from the site of the puncture to the base of the skull; others are dizzy; still others have moderate pain or aching along one or the other sciatic region, and a few have a marked, but painless paraplegia. All these results are transitory, the longest observed lasting about five minutes. They are, however, exceptional, most patients experiencing no unpleasant after-effects whatever. Seven of the patients who are the subjects of this report, invariably arose from the table and walked from the room in their usual manner. The remaining one (Case VI) tottered somewhat upon being helped to her feet, but in less than a minute regained her usual gait.

3. The eight cases recorded received epidural injections but once weekly, while Cathelin (*op. cit.*) makes them as often as every two days. The patients of the Manhattan Hospital West could thus far not be studied oftener than above recorded, because (1) the exigencies of private practice did not allow more frequent visits to the hospital than once a week; (2) at some of these visits one or another of the patients under observation was either menstruating, had diarrhœa, was in an epileptic convulsion, or was too disturbed mentally to be placed in position for epidural injection. But the results so far obtained encourage new arrangements whereby the patients can be seen more frequently than hitherto. The outcome thereof will be made the subject of a future report.

Though the cases studied have been few, the following deductions seem warranted:

1. That epidural injections with decinormal salt solution offer the most promising results in abnormalities of urination due to faulty vesical innervation.

2. That incontinence of urine, enuresis, excessive frequency of urination (unless due to other pathological conditions) can at least be ameliorated by epidural injections.

3. That, cautiously performed, epidural injections are in no wise dangerous to the patient.

4. Epidural injections are no more painful than any hypodermatic injection with a mild solution.

5. Epidural injections can be performed by anyone who follows the technique outlined, and is alert to those anatomical variations which are so frequent in the region.

6. The immediate effects of epidural injections are very rarely even disagreeable.

---

## NITROUS OXIDE IN THE PRODUCTION OF SURGICAL ANÆSTHESIA.*

By IRVING A. MEEKER, M.D.,
UPPER MONTCLAIR, N. J.

Before proceeding to the main part of our subject, it may, perhaps, be not entirely devoid of interest to glance very briefly over the history of this agent and note some of the salient points. The gas has been known ever since the beginnings of the science of chemistry, but it remained for Sir Humphrey Davy to make a thorough investigation of its properties, and he, as early as 1799, asserted that in view of its power to destroy physical pain it might probably be of use in surgical operations which did not necessitate too great effusion of blood. For many years, however, no practical application of this knowledge was made, beyond the fact that certain individuals at various times and places did inhale this vapor for the pleasure and amusement of themselves and their friends. It was probably inhaled, however, with a considerable admixture of air, and consequently the so-called stage of excitement was much exaggerated, with the final result that the gas came to be commonly known as laughing-gas.

Finally, in 1844, at an entertainment where the gas formed the principal means of amusement, a dentist, Dr. Horace Wells of Hartford, noted that one of the gentlemen injured his leg while under the influence of the gas, without any sensation of pain whatever. The next day the dentist himself took the gas and demonstrated in his own person that a tooth could be extracted without a trace of pain. He continued to use it in his practice with varying success, but for twenty years more the gas did not come into general use for dental extraction, and so far as its employment in general surgery was concerned, it was almost a century after Sir Humphrey Davy's announcement before the gas came to be used in this connection with any degree of generality.

Nitrous oxide is, under ordinary conditions of temperature and pressure, a gas both odorless and colorless and with a slightly sweetish taste. At a temperature of 45° and under a pressure of 50 atmospheres the gas is readily condensed into a liquid and may be placed in cylinders of steel or cast iron ready for delivery to the consumer. Burning substances thrust into an atmosphere of nitrous oxide burn with greater brilliancy, owing to the relatively increased amount of oxygen present, as the result of the decomposition of the gas by the heat of the burning substances, the quantity of oxygen present being just double that of ordinary air. The heat of the body, however, is not sufficient to produce such decomposition, so that the nitrous oxide alone is not capable of supporting respiration indefinitely. The gas is simply dissolved in the blood—not decomposed. Accordingly inhalation of the pure gas without admixture of air or oxygen produces pronounced states of asphyxia and some have held that its anæsthetic action was due largely if not wholly to the asphyxia resulting from its administration. That this is not the case, however, at least to any considerable degree, is shown by the fact that even when moderate quantities of air or oxygen are administered with the gas, so that the asphyxia is altogether relieved, an entirely satisfactory narcosis may be maintained, thus evidencing the fact that the gases

*Read before the New Jersey Chiron Club.

a true anæsthetic agent, acting in all probability directly upon the central nervous system and not indirectly by a process of partial asphyxiation.

Turning now to the methods of administration, we find that special apparatus is necessary for the successful production of satisfactory anæsthesia, because the agent is in gaseous form, and because any considerable amount of air administered with the gas at the outset seriously interferes with the induction of anæsthesia, if indeed it does not absolutely defeat this purpose. There are many forms of apparatus, but I will not take the time for a lengthy description of any of these more or less complicated pieces of machinery. There are, however. a few points of prime importance in any apparatus of this description to which we may profitably devote our attention for a few moments. In the first place it is necessary to have an accurately fitting face-piece, thus rendering the connection between the respiratory apparatus of the patient and the gas-containing cylinder practically air-tight, with the exception that there should be a valve which when shut allows the passage of the gas and when open cuts off the gas and allows free ingress of air. A set of valves must also be arranged in the face-piece, so that the gas inhaled, with each respiration is exhaled into the outer air. Another essential in the connections is a gas-bag with a capacity of from two to seven gallons, close to the face-piece, from which the patient may draw his inspirations and thus avoid the sensation of suffocation which is likely to result from the effort to breathe through a tube direct from the cylinder, without the intervening reservoir of gas under ordinary conditions of temperature and pressure. In other words, our chief object in the production of a single complete anæsthesia is to exclude air as far as possible and give simply a pure, unadulterated nitrous oxide.

Passing now to the symptomatology of this form of anæsthesia, we find that the period of unconsciousness is very rapidly induced—usually in 20-30 seconds—and that anæsthesia is complete in from 60-75 seconds. Furthermore, as a rule there is no stage of excitement, so-called, and if this does occur, it is usually indicative that air in considerable quantity has been allowed to enter with the gas into the lungs. The symptoms of complete anæsthesia are stertorous respiration, fixation of the eyeballs, insensibility of the conjunctiva, twitching of the extremities and marked cyanosis, which to an uninitiated observer is often little less than appalling. Just at this point, however, the administration is stopped, and during the ensuing period of a minute or a minute and a half any brief minor operation can be done entirely without causing pain. A tooth may be extracted, an abscess evacuated, and adhesions of the clitoris or prepuce may be broken up. If a longer period of anæsthesia is necessary, say from 5-30 minutes, then instead of stopping the administration finally, as soon as anæsthesia is complete, the gas is shut off and a few breaths of air are given, until the cyanosis begins to abate, and the respiration becomes more natural. This result occurs with considerable rapidity, so that by the time two or three respirations have been taken it is necessary to shut off the air and return to the gas until the symptoms of the deeper anæsthesia reappear once more. This process of backing and filling, so to speak, must be continued throughout the time of operation. This method is known as the "gas and air" method, and as it is necessary to give the gas for a much larger proportion of the time than it is possible to give air, the patient is cyanosed by far the greater part of the time and often presents a very uncanny appearance. It is of course readily seen that the carrying on of this form of anæsthesia requires the closest possible attention on the part of the administrator, if he desires to obtain results which are gratifying to the patient, the operator and himself. The signs which require watching are the same as under ether or cloroform, although less dependence can be placed upon the color, because of the cyanosis which naturally occurs with this agent. Sudden and extreme dilatation of the pupil is, of course, a grave danger sign. The pulse is ordinarily little if at all accelerated, and although good and regular, is usually feeble and lacking in volume. The most important point of all, however, which requires attention is the respiration; as the anæsthesia becomes complete the respiration is regular and somewhat increased in frequency, but deep and stertorous. If now the administration be pushed still farther, the breathing becomes feeble, irregular, and of a frequency about one-half the normal. These signs of respiratory failure are of the very greatest importance and should be heeded immediately by a brief cessation of the anæsthetic until the patient returns to a more normal condition, —a change which usually occurs with considerable speed after stopping the gas inhalation. When more than a 30-minute period of anæsthesia is necessary, resort should be had to the use of oxygen in combination with the nitrous oxide. The oxygen, however, is not used intercurrently simply, as is the air, but is supplied from the very inception of the administration. At the outset it is used to the amount of 2 to 3 per cent. and is gradually increased to 10 to 12 per cent. as the anæsthesia progresses—it having been found by experience that such an amount can be given, while yet complete anæsthesia is maintained, without the development of any cyanosis whatever. The proportions, however, must be varied constantly to suit changing conditions—the patient being, perhaps, more thoroughly under the control of the administrator, than with any other anæsthetic. At the same time a correspondingly greater skill and watchfulness are required on account of the rapidity and facility with which these changes may occur. In cases of nephritis this should always be the anæsthetic of choice, as its effect on the kidneys is practically nil.

Another use of nitrous oxide, and that perhaps in which we are all most interested, is its administration as a preliminary to ether anæsthesia. For this purpose there is required some special form of inhaler, such as the Clover-Hewitt, or that of Bennett, which is commonly used in and about New York. When administering the gas in this connection it is not necessary or even desirable to produce a complete gas anæsthesia; on the other hand, the aim should be so to blend the latter part of the gas administration with the beginning of the ether, that the change will be imperceptible to the patient; by this means we avoid the tendency to coughing and strangling, which frequently occurs in the ordinary way of giving ether.

Another feature of value is that the amount of ether necessary for the induction and maintenance of anæsthesia is greatly reduced, thus sparing the eliminative organs of the patient and the purse of the anæsthetist, and, for a similar reason, subsequent nausea and vomiting are much reduced. The so-called stage of excitement is entirely eliminated in the majority of cases, and inquiry after operation will disclose the fact that the patient has had no recollection of anything after the first three or four inhalations of gas until he begins to wake from his anæsthetic sleep. This method is

particularly useful in the case of plethoric and atheromatous individuals, in which it is so necessary to prevent the vascular engorgement which regularly occurs during the stage of excitement. If for any reason it is desired to use gas as a preliminary to chloroform, the sequence should not be direct on account of the cyanosis and respiratory depression caused by the gas. It is perfectly safe, however, to follow the gas with ether, a respiratory stimulant, and the ether in turn with chloroform.

The advantages of nitrous oxide are that marked anæsthesia is rapidly induced and recovery occurs with equal rapidity. With respect to safety, it is probably the safest anæsthetic which we possess, especially for short operations. Colton has reported 100,000 cases without a single fatality. No ill effect is produced on any organ. No elimination is necessary, or even possible, by way of the kidneys or intestinal tract, for by the time the patient awakes practically all of the agent used has been exhaled with the air expired from the lungs.

The disadvantages, while requiring consideration, are not of serious moment. In the first place, the simple gas anæsthesia is very brief, but here the air and oxygen combinations step in to fill the breach. Another item is that of expense, on account of the amount of gas and oxygen required if the operation is a lengthy one; but this is more than overbalanced by the corresponding gain in safety. Occasionally an alarming degree of asphyxia is developed, but I have been able to find no record of a fatal case. Another condition which sometimes occurs is incomplete muscular relaxation, although this disappears, as a rule, very soon after the anæsthesia is well under way.

The preparation for this form of anæsthesia should, when possible, be the same as for other modes. In any event, however, bladder and rectum should be emptied to prevent the occurrence of evacuation during the course of the induced sleep. An empty stomach is likewise a desirable feature, but is not so much a matter of necessity as with chloroform and ether.

Nitrous oxide is contraindicated, as a rule, in all cases of respiratory interference of whatever kind, such as that resulting from the pressure of tumors, paralysis of the respiratory muscles, or stenosis from the presence of croupous membranes or compression from effusions. Fleshy people likewise are bad subjects, on account of the well-known difficulties which they have with respiration. It is also said to be contraindicated in children, although I have seen it administered to children of all ages from six months up without ill effect.

Nitrous oxide is especially indicated in many minor surgical operations, such as incision of felons and abscesses—in short, operations about the rectum, in examination and reduction of fractures, and especially for painful dressings in children or highly strung individuals of older growth. In fact, at the Hospitals for Ruptured and Crippled in New York all children requiring dressings which are at all painful are anæsthetized with this agent. The time required for each dressing is from five to twenty minutes, and if necessary the anæsthesia is repeated daily, and seems to be absolutely without ill effect.

It is generally conceded that nitrous oxide is the safest of all anæsthetics, not even excepting cocaine, and if we look over the list of conditions in which this agent has been used, we find a category long and varied that will undoubtedly be greatly augmented with the development of new devices for the handling of the gas and the increased skill in administration resulting from extensive experience.

## THE TREATMENT OF THE PEDICLE IN OVARIOTOMY AND SALPINGO-OOPHORECTOMY.*

By L. H. DUNNING, M.D.
INDIANAPOLIS, IND.
PROFESSOR OF THE DISEASES OF WOMEN, MEDICAL COLLEGE OF INDIANA.

KEENE, in a private conversation with the writer, remarked that "the treatment of the abdominal incision is a subject of perennial interest." This remark is equally applicable to the treatment of the pedicle or stump in ovariotomy and salpingo-oophorectomy.

McDowell, in 1809, ligated the pedicle of an ovarian tumor with a long thread and dropped the stump back into the abdomen but drew the ends of the ligature out of the lower angle of the incision. In this his usual practice he was followed by Clay‡ of Manchester. Spencer Wells devised his clamp method in 1858, and continued its use through 627 operations until 1878, with a mortality of 20.73 per cent. After a considerable series of failures by other methods, Baker Brown of London adopted the cautery method of treating the pedicle and then dropping it. From May, 1865, to September, 1867, he employed this method forty times with but four deaths, 10 per cent. mortality, and yet Spencer Wells' mortality with the clamp was 20.73 per cent.; still so overpowering was his influence that Baker Brown's splendid results were entirely overlooked and the Wells' method was almost universally followed.

Keith seems to have been the first eminent surgeon to have profited by Brown's lowered mortality. He began using the clamp method of Spencer Wells, but soon found his mortality so frightful that he adopted Baker Brown's intraperitoneal method and introduced glass drainage tube. To these two methods he attributed his low mortality, which was the lowest that had up to this time been obtained. The short ligature was employed early in the history of the operation, but was not generally adopted until recent years.

§Dr. Nathan Smith of Connecticut, in 1821, first employed the short ligature and dropping the stump. He used for the ligature a strip of leather cut from a kid glove. This patient recovered. In 1829 Dr. David Rogers of New York ligated the arteries separately. Dr. Tyler Smith was first to systematically and regularly advocate the complete intraperitoneal ligature. This method is now almost universally adopted.

Such is the brief history of the evolution of the development of the present methods of dealing with the pedicle in ovariotomy. The same principles have been applied to the treatment of the stump in salpingo-oophorectomy. Many modifications have, however, been introduced from time to time.

Mr. Tait's Staffordshire knot for a time had sway, and in the hands of its originator was one element leading to brilliant results. The knot has not been universally adopted, indeed of late years I have not seen it employed in a single instance. The cautery method of Baker Brown has largely disappeared, but the electrothermic method of Skene has with some operators taken its place.

A few years ago the method of crushing the pedicle by the angiotribe of Tuffier was introduced, and while it has not met with universal acceptance there are many able surgeons who employ it in preference to all other methods.

The writer has employed it in a considerable

*Read before the Indianapolis Gynecological Society.
†Biography of E. McDowell, p. 260.
‡Tait's "Diseases of the Ovaries," p. 246.
§Alban Doran, St. Bartholomew Hospital Reports, 1877.

number of cases, and abandoned its use, first, because of fear of hemorrhage; second, because the instrument is a heavy, unwieldly one; third, because of the time required in its use, and, fourth, because it does not yield any lower mortality than the ligature method.

In the use of means of dealing with the pedicle in ovariotomy and salpingo-oophorectomy there are three dangers to be avoided, viz., hemorrhage, infection and adhesions, and the technique least likely to be followed by any one or all of these dangers is the one to be employed, and if I were to ask a group of abdominal surgeons in turn what technique each deemed the most efficient, I would elicit a variety of opinions. One would say we are all striving at the ends above indicated, and one might say he had obtained the best results with silk ligatures, another with catgut, another with the angiotribe, while a fourth would declare in favor of the electrothermal cautery. The operator who is master of any one of these means will obtain excellent results in its employment.

For myself, the greates satisfaction has come to me and my patients by the employment of the catgut ligature, so to enable me to express my views after my own way and to furnish a text for discussion, I propose to state the methods I have adopted in the use of catgut ligature.

Let us consider first the pedicle of an ovarian tumor. An aseptic catgut ligature applied *en masse* to an aseptic pedicle in aseptic surroundings is an ideal method. I have now for some years used a single thread, No. 3 or 4. If the pedicle is small, it is transfixed in the middle by a single thread, carried by a medium sized blunt pointed ligature carrier, tied around the first half, then reversed and tied around the whole pedicle, three knots being tied; both threads are then cut one-third of an inch from the last knot. The pedicle is then severed between the ligature and tumor, far enough away from the ligature to leave a long button. An effort is made to hollow out or groove the center of the button so that the edges of the raw surface of the button may be brought together with fine catgut sutures. Before these sutures are applied, however the arteries of the pedicle are found in the free surface of the button, seized with a pressure forceps and ligated below the bite of the forceps with suitable catgut. Now the raw surface of the button is covered by peritoneum, either by bringing the edges together by sutures or by resorting to the method of Baldwin, viz., by doubling the pedicle over upon itself so that the raw surface shall rest upon the pedicle below the ligature and fastening it there by two or three interrupted sutures. Care must be used in these manipulations to avoid loosening the ligature by straining the knot or by drawing a portion of the stump beneath the ligature. The latter circumstances I have had happen to me a few times, but inasmuch as the work was done in plain sight, the accident was discovered and harm avoided.

This method of treating the stump of an ovarian tumor pedicle is so common that it may seem a work of supererogation to mention it, but after having witnessed work done by many operators I am persuaded that it is not yet time to cease discussing this important subject.

The same principles must be applied in the treatment of the pedicle in salpingo-oophorectomy, yet here slightly different anatomical conditions are present, viz., the pedicle is, as a rule, less vascular and is much shorter, and the stump left by an *en masse* ligature rests in such an exposed condition that if the distal end of raw surface is left uncovered bowel adhesions are more liable to occur than they are in a case of an ovarian tumor.

Tait's method of ligating the pedicle with silk thread, employing the Staffordshire knot, cutting away the appendages and dropping the stump was at first almost universally adopted. This method has, however, with good reason, largely fallen into disuse. For several years now I have not seen the Staffordshire knot applied, and in most instances in which the distal extremity of the stump has been left uncovered by peritoneum, the operator has made a sort of apology by saying that the surface is so small, I do not believe we will have any adhesions to it.

I believe it was Olshausen who first called attention to the dangers of intestinal adhesions to the stump after salpingo-oophorectomy. I have myself observed three cases of this sort, two in my own practice and one in the practice of one of my colleagues. These unfavorable experiences have made me very persistent in my efforts to always close the raw surfaces in the stump. An unhappy experience in losing a patient from slipping of a pedicle followed by hemorrhage and death led me always to see to it that the ligature was so placed that there shall be no tension upon the proximal end of the stump. Of the large number of methods brought forward to do away with the stump, none of them, so far as I know, have been entirely satisfactory.

A method employed by me occasionally for a number of years comes near meeting the requirements, but has in it an element of danger in the hands of the inexperienced operator. This method consists in boldly cutting across the Fallopian tube at the horn of the uterus, then severing the attachment of the mesosalpinx from the under surface of the Fallopian tube, cutting free the ovary from its attachment to the broad ligament and uterus, tying all bleeding vessels, and with a whip row stitch closing in all raw surfaces.

This is a very satisfactory method in the majority of cases, yet one unfortunate experience in having hemorrhage between the folds of the broad ligament led me to see the danger of such free cutting of vascular tissues without mere extensive ligation of blood vessels. In very vascular patients I have sometimes ligated the ovarian artery near the pelvic wall and then had no fear of hemorrhage.

For several reasons the stump method is the preferable one if a sufficiently long pedicle can be found. It is the quicker method and it serves to render taut and more nearly normal the relaxed broad ligament, and thus in many instances aids the accomplishment of the artificial support of a prolapsed or retroverted uterus. This latter is sometimes effected by tying the stump alone. When it is not, the simple plan recommended and practised by Tait is usually quite effective. This is to draw a loop of the round ligament beneath the ligature, encircling the stump so that when the ligature is tied the portion of round ligament is firmly held beneath it and finally becomes united by adhesions to the tissues forming the stump. This is a very effective way of holding the fundus of the uterus forward.

It has seemed to me that in case the patient should vomit much or the bladder should become over-distended, there might be danger, because of the strain upon the ligament, of its pulling from beneath the ligature, thus rendering the constriction of the stump less firm and possibly predisposing to hemorrhage, so of late I have been in the habit of placing a stitch through both portions of the round ligament anterior to the ligature, so as to relieve the strain upon the stump ligature. Of course this method of shortening the round ligaments to over-

come retroversion of the uterus is only applicable in case the appendages are removed from both sides.

The covering of the raw surface of the stumps in salpingo-oophorectomy is a matter of considerable importance, of greater importance, indeed, than in case of ovariotomy. It is more difficult, too, for many times it is difficult or impossible to place the ligature far enough below the ovary to enable one to cut away the whole of the ovary and leave a sufficient button of tissue distal to the ligature to be entirely sure the stump ligature will not slip over it. Here one must exercise his ingenuity. I have employed one or two means with considerable satisfaction. The first one is to leave as much of the mesosalpinx distal to the ligature as is safe, and sever the tube from the mesosalpinx as close to the organ as it can be cut. There is thus left distal to the ligature enough of the mesosalpinx to be drawn over and cover the stump so that every portion of the raw surface is covered by peritoneum which is fastened in place by sutures of fine catgut.

When this method is found impossible I have sometimes been able to bury the stump by the use of a puckering string of fine silk placed as follows: the silk is threaded into a curved round-pointed needle, and is first carried rather deeply through the tissues in the horn of the uterus near the entrance of the fallopian tube, then through the center of the round ligament about an inch away from the uterus, then through the upper border of the broad ligament, then through the infundibulo pelvic ligament, through the posterior surface of the broad ligament below the ligature, and, lastly, through the horn of the uterus near the first insertion of the thread.

Now if the broad ligament is lax and the infundibulo-pelvic ligament of normal length and not attended by inflammatory deposits when the puckering string is drawn upon, the stump is depressed, the tissues included in the puckering string suture will be approximated and the stump entirely buried out of sight. If the broad ligament is thickened and stiffened by inflammatory deposits, as it sometimes is in pelvic inflammation, this maneuver cannot be accomplished. Sometimes, when neither of these methods can be successfully employed, the Baldwin technique is effective when it can be safely applied.

For many years now I have used only catgut for securing the stump and have had no reason to regret the selection of this material. I do not, however, feel it is safe to leave the pedicle, no matter how securely tied, without having ligated with an aseptic ligature each artery found in the pedicle.

---

**Peripheral Neuritis of the Alcoholic Type.**—Leonard Williams says that it is now generally believed that arsenic in the beer in conjunction with the alcohol is the cause of multiple neuritis. He pleads for the re-admission of alcohol on terms of equality with arsenic into the field of etiological probabilities, with a strong recommendation in favor of some other cause or causes to the identification of which there is at present no evidence to point. He reports several cases in support of this view. One, a woman of forty years, had been drinking to excess for some ten years. She had been taking about six bottles of whiskey a week, with an occasional bottle of stout, for over a year. All of these had been openly provided, and it is certain that she was never supplied from any other source. The whiskey and the stout were both examined for arsenic, but the result was negative. She suffered from severe peripheral neuritis, the author being called to attend her in a second attack.—*The Practitioner.*

## POST-GRADUATE WORK IN BUDAPEST.

By WILLARD J. STONE, M.D.,
GLOVERSVILLE, N. Y.

THERE have appeared from time to time, in the various medical journals articles, dealing with post-graduate instruction to be obtained in Great Britain and the continent. Among the best of these may be mentioned an article which appeared in the MEDICAL RECORD of June 21, 1902. This article contained details regarding the various hospitals in London available to the foreign student as well as many of the well-known centers of post-graduate instruction on the continent.

The present article has to do with the city of Budapest—a city in which excellent post-graduate instruction may be obtained, especially by workers along the special lines to be more fully described below.

Budapest, the capital of Hungary, is four hours distant from Vienna by express trains, and has a population of about 600,000 people. The hospitals, of which the three larger ones contain over 2,300 beds, draw from an unusually large extent of surrounding country, and are consequently well supplied with clinical material. In addition to these general hospitals, perhaps the most important centers are the Central Clinics or "Kliniken," which are in reality made up of a number of buildings devoted to the special branches.

These Central Clinics contain from 800 to 900 beds, and all of the departments of the field are here represented. Special mention may be made of the new surgical and the new gynecological sections of these clinics, which embody all the latest ideas of hospital construction, and are admirably equipped. The men in charge of these clinics are very cordial in the reception accorded to visiting colleagues, and offer them many of the facilities enjoyed by themselves.

For those who desire especial training in gynecology, obstetrics, pathology, and diseases of the ear, nose, and throat, Budapest has much to offer. This is largely because this particular field is not overcrowded with special workers, visiting physicians are always welcome, and also because the actual work may be done by the worker himself. This work can, of course, be secured in other cities on the continent, notably in Vienna, but the difficulty attendant upon the overcrowding of the field will be found, perhaps, less evident in Budapest than anywhere else. At this point mention may be made of the fact that although Hungarian is largely used, German without exception, and frequently French and English are spoken by the men in the clinics.

*Pathology.*—Special mention must be made of the excellent pathological institute connected with the Central Clinics, which is undoubtedly one of the best equipped laboratories in Europe, and which was erected some years ago at a cost of $225,000. The autopsies in this particular institute number over 1,000 yearly, and ample opportunity is given to workers in pathology for participation in the autopsies themselves. Visitors are most cordially welcomed by the director, Professor Pertik, and every facility is given by him to those who desire to work along special lines of research. A special working table is allotted to those who contemplate a prolonged stay, and the abundance of pathological material which has accumulated during the last nine years, together with an excellently arranged collection of over 10,000 microscopical sections, is placed at their disposal. The system of recording the daily findings in the post-mortem room is an especially good one, and the reports of the last 8,000 or 9,000 cases,

arranged in a manner easy for reference, will be found a valuable aid to statistical workers.

Professor Pertik's demonstration during the semester is particularly good—since microscopical preparations of the macroscopical material to be demonstrated are fully described, and the mechanism of death carefully considered.

*Gynecology and Obstetrics.*—The "Erste Universitäts Frauen-Klinik," the gynecological section of the Central Clinics—the old Semmelweiss Clinik, is in charge of Professor Barsony. This clinic, being new, is modern in construction, and very well equipped, and contains 100 beds for the obstetrical service and forty beds for the gynecological service. The last yearly report showed 1,542 births with two maternal deaths, while the gynecological service gave a report of 278 in-patients with five deaths. There are 3,000 out-patients attending this clinic yearly.

The finest special hospital in Budapest, if not in Europe, is the new building devoted to gynecology and obstetrics, but which is not connected with the Central Clinics. This clinic is in charge of Professor Tauffer, formerly an assistant of Professor Hegar in Freiburg, and contains 120 beds. The service here is a large one, consisting of about 2,500 hospital and dispensary patients yearly in gynecology, and of about 1,000 births in hospital, and 1,500 out-patient births yearly. Service in this hospital is offered as follows: first month, as resident interne in obstetrical service; second month, on out-patient obstetrical service; third month, as interne in gynecological strvice.

This, of course, refers to living in the hospital, and includes the ordinary room and living requisites in addition to a small monthly fee.

*Surgery.*—The opportunities given to post-graduate guests for operative work is necessarily limited. In this connection the word "guest" is to be taken literally, differing markedly in this respect from many of the other centers of instruction in Europe, since the so-called "private courses," common to Vienna and Berlin, in which a small class is made to cover the ground under an assistant, are made remuneratively worth the assistant's time. These opportunities will, however, probably be found less difficult to obtain here than elsewhere by those who are able to spend a few months in the service either of the surgical section of the Central Clinics or in one of the many hospitals. Guests will be appointed "externists," which implies actual service in the dispensary, and after two or three months of such service, participation in the major operative cases.

Professors Dollinger and Reczius are in charge of the surgical section of the Central Clinics. This section contains 180 beds and has 1,400 in-patients yearly, with from 800 to 900 operations. The dispensary service is divided as follows: (1) General surgery, 5,000 patients; (2) Orthopedic surgery, 2,000 patients; (3) Genito-urinary surgery, 1,000 patients.

Professor Navratil is in charge of the surgical work in St. Rocas Spital. This contains 100 beds; the in-patients number 1,500, while the dispensary service numbers 11,000 annually.

*Laryngology and Rhinology.*—In this department work may be secured in the cliniks of Professors Irsai, Onody, and Navratil. For those who wish to study tuberculosis of the larynx, the Clinik of Professor Irsai may be especially recommended, as this clinik is particularly rich in material from this standpoint, and Professor Irsai is exceptionally liberal in apportioning operations. The daily average of patients is from sixty to seventy. The clinik of Professor Onody is to be recommended for the study of the affections of the nose and the accessory sinuses. His researches along the lines of the anatomy of the sinuses in recent years make his clinik an especially interesting one from this point of view. The material here is somewhat less than in the one mentioned above.

Professor Navratil holds the chair formerly held by Czermak, who, perhaps, in the early days of laryngology did more to advance the science than any one else. Attached to this clinic are twenty-four beds, and the yearly number of in-patients is about 550. The dispensary service numbers about 3,400 patients yearly.

It is not intended in this short article to imply that at last the Mecca for post-graduate work has been found. The author merely wishes to note that for those workers in the field of gynecology and obstetrics in pathology and upon affections of the nose and throat, who, not willing to content themselves with a mere view of the work, but who are anxious to assist or do the work themselves, Budapest will be found to supply a certain want.

English colleagues desiring further information on this subject may confer with D. Louis Cairus, M.B., 2 Overdale Villas, Langside, Glasgow, Scotland, who is, in large measure, responsible for the appearance of this descriptive article, and who likewise, from a more extended experience in Budapest, attaches importance to the opportunities offered there. He will be glad to give to anyone who may wish to study in that city more detailed information relative to residence and work.

## A CASE OF VENEREAL WARTS.

By A. P. STONER, M.D.,
DES MOINES, IOWA.

ATTENDING SURGEON TO MERCY HOSPITAL; PROFESSOR OF PRACTICAL THERAPEUTICS, MEDICAL DEPARTMENT; PROFESSOR OF PHYSIOLOGY, DENTAL DEPARTMENT, DRAKE UNIVERSITY.

From a cursory examination of the literature at my command, I am impressed with the opinion that a case such as I am about to report possesses sufficient interest to entitle it to brief mention.

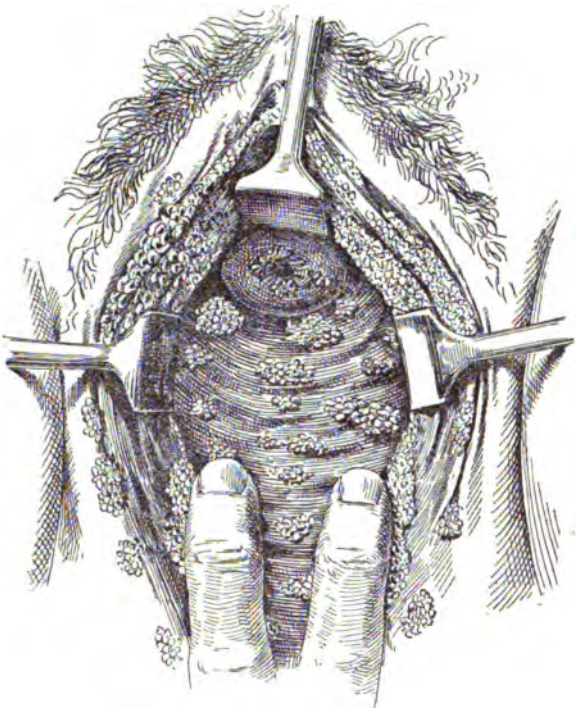
In January, 1901, May H., age eighteen, a domestic, consulted me relative to a discharge and a warty growth upon the external genitalia. Examination revealed a recent attack of gonorrhœa. The discharge from the vagina and urethra was profuse, and numerous condylomata studded the surface of the vulva and a large mass occupied a site adjacent to the anus.

Antiseptic douches were ordered, and on the following day, with local anæsthesia, the warts were removed and their bases cauterized. The douches were continued twice daily, and the parts kept clean and dusted with an antiseptic powder. However, in spite of this care the warts persistently returned. Upon removing them for the second time and they returning, I was led to make a thorough vaginal examination, when I discovered that the vaginal walls were studded with the growths.

The patient then entered Mercy Hospital, and on February 18 the growths were removed and their bases cauterized under ether anæsthesia. The accompanying cut drawn from a photograph shows the condition before the last operation.

Several condylomata occupied the cervix. Speedy work was prevented by hemorrhage, as it was difficult to operate on those situated high up under a continuous stream. So extensive was the involvement of the labia that much of them had to be sacrificed with the removal of the growths. The canal was loosely packed with gauze and a douche of antiseptic solution was used twice daily. The patient left the hospital in a week, since which time I have not seen her.

According to Unna, condylomata should be distinguished from true papillomata, inasmuch as there is not any independent growth of the papilla in condylomata but only an increase of their size from infiltration with leucocytes. The infolding of the epithelium upon the papilla produces the increase in number of the latter; thus the papillæ are



secondarily altered by proliferating epithelium. When condylomata appear upon the mucous membrane of the vulva they usually extend by serpiginous process, or they may appear discretely upon the adjacent integument. It is unusual for them to extend internally within the neighboring organs, but cases are reported of the involvement of the rectum, urethra, vagina, etc., rendering their destruction necessary before a cure can be accomplished.

## CIRCUMCISION IN INFANCY.

By WM. B. HARLOW, M.D.,
KIBBE, CONN.

THE practice of circumcising infants has of late come into some favor. As a Jewish rite handed down from remote antiquity of course nothing can be said against it. It is as sacred to the Hebrews as baptism is among the Christians. Both ceremonies deserve to be respected. But as a medical practice what are the arguments in favor of infant circumcision? The delicate surface of the corona of the glans is provided with innumerable nerve papillæ of exquisite sensitiveness. Nature has provided a careful protection to this surface—the double flap of foreskin which is common to male animals of the higher as well as the lower species. Why should this be torn or cut away? There are rare instances, it is contended, in which phimosis or inability to move the foreskin at will might in adults cause inconvenience and also tend to produce epithelioma or surface cancer. Yet it is known to be the case that connection has been complete when this temporary removal of the foreskin does not take place. A mother was told by her physician to draw down the foreskin when bathing her infant boy and wash beneath it. She was distressed because the prepuce would not pass over the corona and was then told that the child should be circumcised at once. It is not intended by nature that the generative organs of an immature child should thus be tampered with. What surer way to cause premature excitement, susceptible as some are even in extreme youth to any manipulation of the organs? That unwise adviser of the mother might as well have told her to lift up the eyelids of her child and wash the sensitive mucous membrane that lines them or to syringe out the ears when no foreign substance had irritated them. There is no possibility of any irritating collections occurring beneath the prepuce until maturity, and not then until the semen has been called out and allowed to set back under the skin. It has been asserted that circumcision will prevent self-abuse. How untrue this is may be known by the fact that erections may be produced as readily without the foreskin as with it, and boys who are inclined to the habit of course may produce the desired sensation by manipulating other parts of the organ as well as the prepuce.

The foreskin of infants as well as of adults who have remained continent usually extends beyond the corona, and is not only a nice protection from injury but a guard against many excitements of the organ.

Circumcision produces an ugly mutilation of the penis, of which one arrived at man's estate, unless he were a Hebrew, might feel greatly ashamed. It would be cruel to inflict unnecessarily such a mutilation upon a helpless child. The statue of a Greek with such a deformity upon it would be turned from with loathing. Let the operation be performed only upon adults, with their own consent, and when it is a necessity.

---

**Rabies in London.**—Every reported or suspected case of rabies in London is inquired into and a necropsy made by one of the council's veterinary inspectors. Whenever the inspector is of opinion that the dog was rabid, or in the event of any person or animal having been bitten by a suspected rabid dog, a further examination is made on behalf of the council at the Royal Veterinary College, or the Brown Animal Sanitary Institute. During the past year necropsies have been made in twenty-eight suspected cases, in eight of which further experiments were conducted, but in no case was any evidence of rabies found.—*British Medical Journal.*

**The Use of Opium in the Carditis of Children.**—Alexander Morison holds that among calmative agents there is none more powerful than opium, when there is no idiosyncratic intolerance of the drug, and when it is used with due care in children, in view of this special susceptibility to its action. The younger the patient, naturally the greater is the care necessary in its use, but even young children when excited locally and generally by an actively irritative process, can tolerate larger doses than in normal circumstances. Indeed the physiological consequences of inflammatory reaction resemble, in a measure, the phenomena caused by agents known to be antagonistic to the action of opium. The quick pulse, the dilated pupil, the suffused skin, the uneasy sleep, or even wakefulness and delirium of the carditic child, may be likened to the poisonous effects of the belladonna group of agencies. It is under these circumstances that opium finds its most beneficial application. In carditis, the author holds that the mechanism by which some of the measures used tend to save life is by their action on the cardiac nervous system, that they are avowedly directed against effects not a primary cause, and that although they may not directly affect the course of an inflammation (a point not proved), they may maintain life until the conflagration has burned out, or the protective processes of the body eliminated the intruding cause of the disease. Among such measures the author would give a prominent place to opium.—*The Edinburgh Medical Journal.*

## PERIODICITY OF DIPHTHERIA AND ITS CAUSES.

IN a pamphlet on "die Periodizität der Diphtherie und ihre Ursachen" (Berlin, 1903), Dr. Adolf Gottstein discusses the factors which determine the form of the curve of diphtheria epidemics. Of recent years almost all study of infectious diseases has been from the bacteriological standpoint, which, while excellent enough, has, nevertheless, its limitations; and there are some questions for the solution of which it is not suited and for which recourse must be had to older methods. In epidemiology the need for the employment of accurate quantitative methods is insisted upon. The author's deductions are based upon the mortality statistics of several of the German states. His studies show that the curves showing the ravages of epidemics in general are dependent for their form upon the interaction of several factors, all of which are to be determined empirically. The first (*a*) represents the average number of individuals exposed to the contagium generated by one patient during the whole period of contagiousness. The second (*c*) represents the percentage of non-immunes so exposed, who actually develop the disease. And the third factor which affects the form of the curve, is the length of time which a patient remains capable of infecting his environment. Even when each patient is in a position to offer contagium to more than one individual (that is, when *a* is greater than 1), the epidemic does not necessarily increase, as it is only when the product *ac* is greater than 1 that it must do so. Both of these factors are, it will be noted, symbols of very real conditions, and they afford some indications for sanitary measures. Thus when *a* is very large and *c* very small, emphasis should be laid upon measures tending to combat individual susceptibility; whereas under reverse conditions measures directed toward destruction of the contagium offer better promise. Applying the above factors to the explanation of the curve exhibited by measles, we find that in this disease *c* is almost equal to 1, more than 95 per cent. of exposed non-immunes contracting the disease. This fact, taken in connection with the short period of incubation (that is, the rapid rise of contagiousness), shows that the disease must grow into an epidemic, provided only that each patient is in a position to offer contagium to one (or a little more than one) individual on the average. In other words, the measles curve must show, as it does, a rapid, sharp rise; and, as the available non-immune fuel must be soon exhausted, the descent must be almost as sharp. And the periodicity of the principal waves find their explanation in the mode of transmission, the seven-year-old school recruits usually being the first attacked, and carrying the disease into the home where the younger children are infected, and thus rendered immune. Whence a cessation till a new non-immune infant population appears.

The question with regard to diphtheria is, however, quite different. A study of the diphtheria epidemics of the last three centuries has brought to light this peculiarity, that for several decades the disease recedes completely; so completely as practically to be for both profession and laity an unknown disease. Then, very gradually, at first sporadically and in small areas, it makes its reappeareance and is recognized only by physicians familiar with medical history. Then very rapidly, but with recessions and new advances, it increases, and somewhere in the second decade reaches an extremely high point and constitutes a fearful scourge for childhood. About a decade and a half later the disease decreases, to vanish as completely as before. Kussmaul's anecdote is characteristic. Familiar with diphtheria at Paris and on the Rhine, he was astonished never to see it postmortem at Vienna in 1847, where the prosecutor explained the disease as a French invention. A little more than a decade later diphtheria invaded Germany, and thirty years later numbered its victims by tens of thousands. Analyzing now the curves representing the mortality from diphtheria, they are shown to present a chief high wave, preceded and followed by one or more waves of secondary magnitude. The chief wave corresponds, of course, to the height of the epidemic. But the author's analysis reveals the extremely interesting and important fact that whereas the crest of this wave represents approximately an equality of mortality as regards the different ages of childhood, the waves of the second magnitude show a sharp difference; those preceding the chief wave representing predominantly a mortality of the youngest children, while those succeeding the chief wave represent predominantly a mortality of the older children. This is, however, not all. These older children, who contribute so largely to the mortality denoted by the secondary waves succeeding the chief wave, are children whose years of birth correspond to those of the younger children whose mortality furnished the bulk of that denoted by the secondary waves preceding the chief wave. From these facts we begin to get a clue to the true meaning of the peculiarities in the periodicity of diphtheria epidemiology. For we see that the mortality of the youngest children (first comers of the comparatively immune generation) has already reached and passed its maximum and sunk again to a comparatively low ebb, at a time when the total mortality for all ages is still exceedingly high. Since it is a disease, one attack of which does not protect against subsequent attacks, the explanation of the peculiarities of the diphtheria curve is, remembering the above facts, now to be sought in the biological field, namely, in the direction of an alternation of a comparatively non-immune generation with a comparatively immune generation; the latter being the offspring of parents who have withstood the ravages of the disease; in other words, of a generation comparatively destitute of susceptible individuals, owing to a continuous,

progressive, and fairly thorough weeding out of the susceptibles before the period of puberty.

That such a progressive weeding out process has been in operation upon the human race is shown by statistics. Thus in one of the worst epidemics, the Hamburg cholera epidemic of 1892, though in all probability a majority of the population was in contact with the contagium, only 3 per cent. contracted the disease. And with diphtheria, at the height of the epidemic, the most susceptible generation does not lose more than about 5 per cent. of its members under the age of five. At least 90 to 95 per cent. (and under favorable circumstances as high as 98 per cent.) of all children possess an inborn immunity against diphtheria; an immunity of so high a grade that they are able to stand without danger to life (and often without the development of symptoms) exposure to its contagium, an exposure which the author has proven to occur at least two or three times before the age of ten. While this may seem surprising, in reality it is not so exceptional. For, to compare again one of the worst epidemics, the Hamburg cholera epidemic of 1892, though it was probable that a majority of the population there was brought into contact with the contagium, only 3 per cent. actually developed the disease, and only 1.5 per cent. died. Great differences exist in the susceptibility of different individuals toward diphtheria, as both Eigenbrodt and Gottstein have shown. Moreover, a sharp line is to be drawn between acquired and inherited immunity. Thus the immunity against measles, smallpox, etc., acquired as the result of an attack, is never transmitted to the offspring, who are just as susceptible as their parents were. The reverse is, however, the case with inborn immunity. This is carried over, as a race trait, to the offspring. The gradual reappearance of a generation susceptible to diphtheria comes about through the fact that marriage qualifications bear no relation to immuneness (the members of the most susceptible families inter-breeding with those of less susceptible ones), and to a partial intermixture of the alternate generations through the somewhat earlier marriage age of the females.

We thus reach the conclusion that the periodicity of diphtheria is due not to variations in the virulence of the contagium, but to fluctuations in the susceptibility of the human organism. Our analysis further shows that besides the process pointed out by Hoppe, by which saprophytes gradually become true parasites, we must recognize the co-existence of the contrary change by which (through continued symbiosis, accompanied by a progressive weeding out of the more susceptible individual hosts), some of our parasites must come to be harmless to the surviving insusceptibles. And with regard to some microorganisms, indeed, we would appear to have almost reached that stage. Thus the colon bacillus, streptococci and staphylococci, and the pneumococcus live without producing disease on our mucous membranes, and involve grave consequences only when, under special conditions, the resisting power of the organism is lowered. Even then they no longer produce epidemics, but only diseases which are limited solely by the reactive power of the organism. Toward Löffler's bacillus this process of adaptation has proceeded so far that over nine-tenths of the human race are born into the world with the needed immunity.

## PRIVILEGED MEDICAL COMMUNICATIONS.

THE *Boston Medical and Surgical Journal* of September 3 contains three well-written and instructive articles dealing with the above subject. The first is contributed by Dr. David W. Cheever of Boston. "The highest legal authorities in England," says the writer, "have decided that medical men enjoy no special privilege with regard to secrets of a professional nature. In other words, no practitioner can claim exemption from answering a question because the answer may or would involve a violation of secrecy, or even implicate the character of his patient." The law of Massachusetts closely follows the English law, as do all the New England States, as well as Alabama, Delaware, Florida, Georgia, Mississippi, North Carolina, New Jersey, Pennsylvania, South Carolina, Tennessee, Texas, Virginia, and West Virginia.

New York State, however, is entirely different in the legal limitations it places upon the evidence of a medical witness, for its law reads as follows: "No person duly authorized to practise physic and surgery shall be allowed to disclose any information which he acquired in attending a patient in a professional capacity." This law was subsequently amended so as to allow a physician to testify, in cases of wills, as to the mental or physical condition of the deceased, except confidential communications and such as might disgrace the memory of the patient. Twenty-two States follow New York, while as to the remaining States, the writer is not certain with regard to the law respecting the question. Dr. Cheever points out that the English law places a medical witness in an anomalous and cruel position. The law lays down the dictum, that a medical man when cross-examined in a court of law is bound to answer any questions which may be asked concerning his patient, and every instinct of honor, propriety, and decency forbids him to follow such a course. The writer proposes, in order to reconcile these difficulties, that "It shall be considered unprofessional for a physician to divulge anything confided to him by a patient, unless (1) with the patient's consent; (2) to defend himself when accused; (3) to expose crime.

The second paper is by Mr. Walter Sorren of Brookline, Mass., who treats of the question from the standpoint of the lawyer, referring solely to the workings of the New York law. It is an elaborate exposition of all the legal niceties involved in the matter, a number of cases on each point being cited, so that the ordinary individual as well as the medical practitioner can form his own opinion as to the working of the law. The article is too long and somewhat too intricate to be more than briefly commented upon here. Nevertheless, it would appear that although the writer considers the existing law of New York State relating to testimony of medical witnesses is by no means perfect, yet he is inclined to doubt whether a new law could be framed which prevented more injustice than is now caused by the present one.

The last paper is by Mr. Frederick J. Stimson of Dedham, Mass., and is entitled "Privileged Communications to Physicians." This writer draws attention to a very important fact, that while the common law of England, followed by so many States in this country as to the testimony of medical witnesses, states that such a witness must answer

any questions with regard to his patient which may be put to him, yet a large discretion is permitted to the judges in their conduct of cross-examinations. Indeed, this discretion is so great, particularly in States where there is no statute, that the judges shape the law.

Mr. Stimson is of the opinion that the common law—interpreted as broadly as it generally is—is, on the whole, preferable to a hard and fast code system. In the common law, he thinks, that the vagueness of discretion left to the judge is possibly of advantage. "Under the Code System," he writes, "nothing is certain that is not in the code. No discretion to be strict or to be lenient can possibly be allowed the judge; and until every sentence, every word, every punctuation mark, has been the subject of a court decision, we cannot be certain of what the law is."

The writer, therefore, deems it wiser to leave the whole matter to the common law, but if any statute is adopted, he would recommend a combination of the laws of Pennsylvania and North Carolina; that is, adopt the Pennsylvania principle that the privilege extends only to civil cases, and this with the exception of the competency of persons making a will, and the very luminous phraseology of the North Carolina Statute, which substantially states the common law—that is, allows the judge to determine when the communication by physicians of knowledge acquired while attending the patient is necessary for a proper administration of justice.

There are, undoubtedly, many forcible points to be brought forward in favor of the common law and of the code system as they relate to medical witnesses. When the judges are well-educated men, thoroughly versed in historical legal education, then the common law is sufficiently effective and, although susceptible of improvement, answers the purpose in a satisfactory manner. On the other hand, if as happens occasionally, the judges are ignorant, and know but little of precedent, the code is better suited to the exigencies of the situation, for the course to be pursued is, to a great extent, marked out, and pitfalls can be more easily avoided by the occupant of the bench.

## THE WORKING OF THE NEW YORK STATE DISPENSARY LAW.

*Charities* of August 29 contains an article by Dr. Stephen Smith, Chairman of the Committee on Dispensaries of the New York State Board of Charities, on the working of the dispensary law. This law was passed in 1899 and sought to regulate the establishment and operation of dispensaries by placing them under the supervision of the State Board of Charities. The statute furnishes a legal definition of what constitutes a dispensary and the procedure under which dispensary licenses may be granted; it directs the formulation of rules and regulations by this board in accordance with which dispensaries shall furnish, and applicants receive, medical relief and medicine; it provides for visitation and inspection by the State, the revocation of licenses for cause and penalties for failure to observe the rules and regulations.

Dr. Smith presents statistics showing the number of dispensaries that have been licensed within the State, the attendance of applicants at the licensed dispensaries and a comparison with statistics obtained in former years.

During the year ending September 30, 1902, five new dispensaries were licensed in New York City, and three new dispensaries located elsewhere in the State were also licensed. Two dispensaries discontinued dispensary work during the year in Greater New York, and three elsewhere in the State.

On September 30, 1901, there were 92 dispensaries in Greater New York and 28 elsewhere in the State, and on September 30, 1902, the number of dispensaries in Greater New York had been increased to 95, and 28 were located elsewhere in the State.

The number of persons treated for the year ending September 30, 1901, was, in Greater New York, 871,783, and for the year ending September 30, 1902, 889,157. The number of persons treated during the same periods outside of New York City was 34,577 and 27,881 respectively, making a grand total for the entire State, in 1901, of 906,360 and in 1902, of 917,038.

Statistics show that the movement of population at dispensaries exhibit a marked tendency toward Manhattan borough. The explanation of this preference for Manhattan on the part of those who seek medical aid at dispensaries, is that the majority of the large hospitals and medical school dispensaries are in that borough, and because the large medical schools create a demand for material for clinical instruction.

It is interesting to note that a considerable proportion of the increase of cases treated at dispensaries during the past year in New York City can be traced to the prevalence of eye affections. So ripe was trachoma among school children, that it was found necessary to open a special dispensary in Manhattan borough to stamp out the epidemic.

One rule which is more or less disregarded in the management of dispensaries is that which orders an investigation to be made of every applicant's financial position, whether he or she is able to pay either personally or by parent or guardian. When, however, it is understood that 90 per cent. of the applicants pay an "entrance fee" while some institutions make a uniform charge ranging from ten cents to twenty-five cents, there is less cause for surprise at the laxity shown in investigating the ability of the applicants to pay a reasonable fee.

Dr. Smith very rightly criticises adversely these methods, first on the grounds that the value of professional medical attendance is thereby unduly cheapened, and secondly because the charge made prevents the institution from refusing its benefits to persons who in reality are able to pay considerably larger fees for the service rendered or employ a private physician.

On the whole, the writer is of the opinion that the New York State Dispensary law has proved effective and has fulfilled in a satisfactory manner the objects for which it was created.

**An Early English Apothecary.**—Anderson, in the "History of Commerce," 1319, states that King Edward III, in the year 1345, gave a pension of sixpence a day to Coursus de Gaugeland, an apothecary of London, for taking care of and attending His Majesty during his illness in Scotland, this being the first mention of an apothecary in the Fœdera.—*National Druggist.*

### Ferrous Sulphate as an Antiseptic and Germicide.

Bulletin 15, issued from the Hygienic Laboratory of the Public Health and Marine-Hospital Service, is by Assistant-Surgeon Allan J. McLaughlin, and treats of the antiseptic and germicidal properties of ferrous sulphate. This chemical substance has long been extensively used for the disinfection of animal excreta, chiefly on account of its cheapness and ease of application. The writers upon the subject, according to Dr. McLaughlin, are few in number, and by no means agreed as to the value of ferrous sulphate as a disinfectant and deodorant. The majority, however, give it but faint praise. Sternberg found that a solution of 20 per cent. failed to destroy micrococci and putrefactive bacteria. Later he found that 10 per cent. failed to kill pus cocci, but was fatal to micrococcus tetragenus after two hours' exposure. He also found that a solution of 1:200 prevented the development of micrococci and of putrefactive bacteria in bouillon placed in the incubator for forty-eight hours. Koch found that a 5-per-cent. solution failed to destroy anthrax spores in six days. Foote found, as a result of a series of experiments, that the substance was of little use as a means of disinfecting fæces. McLaughlin carried out a series of experiments in order to test the antiseptic and germicidal efficiency of ferrous sulphate, and arrived at the following conclusions: "Sulphate of iron does not show any restraining influence over the development of putrefactive changes unless it constitutes more than 2 per cent. of the mixture. It does not permanently restrain the development of putrefactive changes unless it constitutes at least 5 per cent. of the mixture. As a germicide it has little or no action, even when applied under the most favorable conditions for disinfection." Tested upon fæces it failed to disinfect after three days, although intimately mixed with the fæces, and applied in saturated solution and in double the bulk of the material to be disinfected. It seems, therefore, that copperas or sulphate of iron is of no real value as a disinfectant. The strongest solution has either no disinfectant action at all, or its disinfectant action is so slow and uncertain that its demonstration might be a matter of interest, but certainly could not be of practical value.

---

### The Operative Treatment of, and the Mortality from, Chronic Pancreatitis.

During the past few years much has been learned concerning chronic pancreatitis. Dr. W. Hale White, writing in the *British Medical Journal*, July 18, says that the most common form of this disease, is an enlargement and induration of the pancreas, such as is constantly seen in a nutmeg liver, or in the large tough kidney associated with cardiac disease. Mr. Mayo Robson—as he mentions in the address in Surgery delivered before the British Medical Association this year—was the first to draw attention to the fact that many cases described as cancer of the head of the pancreas, and leading to chronic jaundice, which ended fatally, were really cases of chronic pancreatitis that could be cured by draining the pancreatic duct indirectly through the bile passages.

Dr. Hale White, however, records a case of chronic pancreatitis which, in his opinion, teaches that an operation probably, and diverting the bile from its normal tract certainly, are not always necessary; and, secondly, which shows that chronic pancreatitis is rarely fatal. The case in question was diagnosed as carcinoma of the head of the pancreas and an operation was decided upon. The abdomen was opened and the head of the pancreas was found to be so large and hard, that—as this was considered to indicate that the patient was suffering from carcinoma of the head of the organ, the abdomen was closed. The bile passages were not drained in any part. The operation took place in July, 1901, and in June of this year the man operated upon reported that he was in excellent health. This instance, thinks Dr. White, suggests that in some cases operation has been performed unnecessarily. As to the point whether chronic pancreatitis is often fatal, the author, from a close and careful study of the post-mortem records of Guy's Hospital, from 1861 to 1901, in which period 1,900 necropsies were made, has come to the conclusion that chronic pancreatitis is very rarely a fatal disease. "Probably," he says, "not being responsible for more than one or two out of nineteen thousand deaths, and certainly not being responsible for more than four."

---

### Calomel in Tuberculosis.

In the *Wiener medicinische Wochenschrift*, Nos. 7-10, Dr. Martell speaks highly of the value of calomel in the treatment of incipient tuberculosis. Treatment against a specific microbe, with its specific localization, must be specific and antitoxic, and the elective action of mercury toward the glands, its incitant action on the tissue cells, and its power of combining with metabolic toxic products, qualify it for this rôle. Mercury is no specific against tuberculosis, but it stimulates the biochemism of the infected territories to a higher grade of activity. The fittest preparation is calomel. The indications are the removal of the vasomotor paralysis, the fixing of the poisonous metabolic products, and the fluidification, and ultimately the elimination of the morbid substances. After the administration of calomel we see from day to day a progressive increase in the secretion from the lungs and the intestine. At the beginning the dose should be 0.01 (gr. $\frac{1}{6}$), increased to three powders each of 0.02 (gr. $\frac{1}{3}$), or even more should constipation be present, returning to two or three powders when regularity in defecation is established. With the internal administration, inunctions are to be begun, each inunction being preceded by a washing of the skin with tincture of green soap. The mouth must, of course, be carefully washed, and upon the least painfulness washed with corrosive sublimate 0.02, alcohol 50, aquæ melissæ 500. From about the fifth day of treatment the tuberculous matters appear in the stools in the form of slimy, fibrinous or purulent, yeasty, and foul smelling masses, whose excretion in women is accompanied by a fetid, yellow purulent discharge from the genitals; necessitating rest in bed, or at least absolute rest from exertion. Children with a strong hereditary taint, especially if the brothers or sisters have been tuberculous, should be subjected to the calomel treatment (0.003, or gr. $\frac{1}{20}$ three times a day) by way of precaution; the treatment being continued until the dejections are absolutely free from foul odor and mucopurulent admixture. Children bear the treatment well, and the author believes that he has saved many by it from certain death.

---

### Salt Solution Enemata after Renal Operations.

In the *Maryland Medical Journal*, August, attention is drawn to this subject. The fact is pointed out that in the Johns Hopkins Hospital Reports for August, 1898, was published the result of a series of experiments designed to determine the effect of enemata of salt solution upon the specific gravity of

urine. The outcome of these experiments demonstrated the marked diuretic value of salt-solution enemata, and suggested that it would furnish a valuable method of flushing out the kidneys, in conditions in which such flushing out is of prime importance. Nephrectomy, nephrotomy, and nephropexy are among the most important of these conditions, but the method it was thought might be used with success in all operations in which ether was the anæsthetic, and in which a diminution in urinary secretion existed. The writer of the article goes on to say that, as a result of these observations, it has been the custom at Dr. Kelly's private hospital to carry out the following regimen in all cases, in which the kidney has been operated upon: one pint or more of salt solution is administered by rectum every six, eight, or twelve hours, according to the necessity of the case, for a number of days after operation. In the six cases of nephrectomy, and the twelve or more of nephropexy in which this procedure has been carried out the secretion of urine has been very free, very often even larger quantities than normal being passed. Besides this, it was noteworthy that the convalescence of these patients was much more comfortable than in the usual run of renal patients, the nausea and headache especially being markedly diminished. When the kidney has not been operated upon directly, but when ether is used and there is a diminution in urinary secretion, there is no need to give the enemata so frequently. The article concludes by insisting upon the great value of the systematic use of salt-solution enemata at frequent intervals not only in cases in which operation upon the kidney has been performed, but also in all cases in which ether, an anæsthetic peculiarly irritating to the kidneys, has been used, and even in a large number of medical cases in which it is essential to promote diuresis rapidly and effectively.

---

### Ship-bred Mosquitos.

Although few men accustomed to weigh evidence and not blinded by prejudice now doubt the agency of mosquitos in the propagation of malaria and of yellow fever, there are still some facts alleged by objectors to this doctrine which are not easy of explanation. One of these is the occurrence of ship epidemics of yellow fever after seemingly thorough disinfection and before the vessel has again entered an infected port. An interesting fact which might serve to account for some such cases is related by Dr. Andrew Balfour of Khartoum in the *Journal of Tropical Medicine* for August 15, 1903. He says that while searching for specimens of mosquitos he was led to inspect the steamers which ply on the Blue Nile and the White Nile and which are perfect hotbeds of these insects. The reason for their presence in such numbers was soon apparent, for he found the bilge water swarming with larvæ, which in some cases were present even in the oily water standing in the engine rooms. These larvæ were of two species of *Stegomyia*, and there were no larvæ of *Anopheles*, although that mosquito is a frequent passenger on the boats. The yellow-fever mosquito, it appears, is a less fastidious breeder than the malarial, and its larvæ will flourish in filthy water which would be fatal to the young of *Anopheles*. Measures are to be taken to rid the steamers of their mosquitos, but evidently fumigation alone will not accomplish this object, since some at least of the larvæ in the bilge would probably survive the process. In that case, assuming that the female imago can transmit the parasite, whatever it may be, to the offspring, it is evident that simple fumigation could not absolutely free an infected ship of its disease-bearing stowaways.

## News of the Week.

**State Board of Medical Examiners of New Jersey.**—The regular examination of the State Board of Medical Examiners of New Jersey will be held at Trenton, N. J., on Tuesday, Tuesday evening, and Wednesday, October 20-21. Application for admission to this examination should be made before October 10. Applicants must possess a high-school diploma issued after four years of study, or its equivalent as determined by the State Superintendent of Public Instruction, and must have had four courses of medical lectures of seven months each in different years.

**Civil-service Examinations.**—The State Civil Service Commission has called examinations to be held October 17, 1903, for the positions of apothecary, trained nurse, physician (male) and woman physician in State hospitals and charitable institutions. Application for these examinations must be made on or before October 12. Full particulars of the examinations and blank applications may be obtained by addressing the Chief Examiner of the Commission at Albany.

**The Henry Phipps Institute** for the study, treatment, and prevention of tuberculosis has arranged for the coming fall and winter a series of lectures by well-known physicians on the various phases of tuberculosis. Some of these lectures will be more or less popular in character, and all will be free to the public. The auditorium of the Witherspoon Hall at Juniper and Walnut streets, Philadelphia, has been selected for the purpose, having a seating capacity of nearly twelve hundred people. The first of these lectures will be given by Dr. E. L. Trudeau of Saranac Lake, New York, during the last week in October, his subject being "The History of the Development of the Tuberculosis Work at Saranac Lake." The following gentlemen have been invited to give the subsequent lectures: Dr. Pannwitz of Germany, in November; Dr. William Osler of Baltimore, in December; Dr. Calmette, Director of the Pasteur Institute at Lille, France, in January; Dr. Herman M. Biggs of New York, in February, and Dr. Maragliano of Italy, in March. All of them have accepted with the exception of Dr. Calmette, who will come if it is possible for him to leave his work in connection with his institute and the International Congress on Tuberculosis to be held in Paris in 1904. Subjects and exact dates will be announced as soon as possible. The director and members of the staff of the Henry Phipps Institute extend a most cordial invitation to the profession in general to attend these lectures. It is greatly desired that this inaugural series of lectures given by these gentlemen will prove a success and be largely attended. The following additions to the staff of the Henry Phipps Institute have been made: Dr. M. P. Ravenel has been appointed Assistant Medical Director and Chief of the Laboratory; Dr. E. A. Shumway has been appointed Ophthalmologist, and Dr. J. F. Wallis has been appointed Dermatologist. The Medical Director of the Institute is Dr. Lawrence F. Flick.

**The Cumberland Valley Medical Association.**—The physicians of Cumberland Valley, including Cumberland and Franklin Counties in Pennsylvania, and Washington County in Maryland, met at Mont Alto, Pa., on September 8, and organized the Cumberland Valley Medical Association. The membership is limited to members of the County Medical Societies of the territory involved, which includes the Cumberland Valley lying between the Susquehanna and Potomac Rivers. The follow-

ing officers were elected: *President*, Dr. Robert W. Ramsay; *First Vice-President*, Dr. James Evelyn Pilcher; *Second Vice-President*, Dr. T. H. Weagley; *Third Vice-President*, Dr. J. W. Humrichouse; *Secretary*, Dr. J. J. Coffman; *Assistant Secretaries*, Drs. A. R. Allen, P. B. Montgomery, and C. R. Miller; *Treasurer*, Dr. J. H. Montgomery.

**Vital Statistics of Philadelphia.**—For the week ended September 9 there were reported to the Philadelphia Bureau of Health 82 cases of typhoid fever with 10 deaths, as compared with 135 cases and 9 deaths for the preceding week. There were also 61 cases of diphtheria with 8 deaths, 57 cases of scarlet fever with 6 deaths, and 7 cases of smallpox with 1 death. The total number of deaths was 418, as compared with 370 for the previous week and with 346 for the corresponding week of the preceding year.

**Typhoid Fever Transmitted by Milk.**—An investigation made under the auspices of the Philadelphia Bureau of Health has shown that of seventy-eight cases of typhoid fever in one ward, forty-one occurred among persons who obtained their milk from a single dealer in whose family there were cases of the same disease. Other cases occurred in the customers of another milkman, in whose family also there had been typhoid fever. In both instances the sale of milk was stopped, and a process of general cleaning and disinfection instituted. Other hygienic deficiencies were found, but it was definitely shown that there was no relation whatever between the disease and the filtered water.

**Teaching of Dental Pathology in Medical Schools.**—At the recent meeting of the National Dental Association, held at Asheville, N. C., a resolution was adopted stating "That it is the sense of the National Dental Association that each medical college in the United States should include in its curriculum a lectureship on Oral Hygiene, Prophylaxis, and Dental Pathology." In support of this resolution it is urged that, with the introduction of the teaching of oral hygiene in the public schools, which the Dental Association is striving to accomplish, and the coöperation of medical men who have been specially instructed on this subject, a great stride will have been made toward the prevention of caries of the teeth, not to mention the betterment of the general health which would surely follow an intelligent care of the oral cavity.

**Another Startling Announcement from Chicago.**—The University of Chicago is always pregnant with great facts, and from time to time gives newspaper birth to them. From it have come spontaneous generation, a half promise of corporeal immortality, a cure for tetanus, various other less portentous disclosures, and latest, but we trust not last, is a recipe for bigness. According to the Associated Press report, the usual medium for giving these discoveries to an anxious world, "the age of the race of giants is about to be ushered in again. Henceforth there will be no pigmies, for a wonderful food substance has been discovered in Chicago that makes men and animals grow fast and large. The new food is lecithin. Its qualities have just been demonstrated by a series of experiments by Dr. Shinkishi Hatai, professor of neurology at the University of Chicago. Dr. Hatai experimented with white rats, and by feeding them lecithin made them grow 60 per cent. faster than they grow ordinarily. This was under conditions of atmosphere and general surroundings that were unfavorable. The scientific men say that lecithin will have a similar effect on human beings." The report adds that the professor finds that the growth induced by lecithin is normal and embraces all parts, inducing bigness of heart and of body as well as of head—a most comforting assurance.

**A Trachoma Hospital.**—The Commissioner of Health has decided to establish a hospital for the exclusive treatment of sufferers from trachoma. A large house in the Borough of The Bronx has been remodeled for this purpose, and will be opened as soon as an appropriation to cover the cost of equipment and the salaries of the staff can be secured. At present trachoma patients are being treated at the old Gouverneur Hospital by a staff of physicians and nurses provided by the Board of Health. The number of patients treated there is between 400 and 500 a day.

**Cornerstone of St. Mary's Hospital Laid.**—The cornerstone of the new building for St. Mary's Hospital in Jamaica, Borough of Queens, was laid last Sunday afternoon by the Very Rev. Mgr. McNamarra, Vicar General of the Diocese of Brooklyn. The hospital building when completed will accommodate about 300 patients. The institution, which now has rather cramped quarters, is conducted by the Little Sisters of the Order of St. Dominic.

**The International Congress of Hygiene and Demography** was held in Brussels September 1–8 under the presidency of M. Beco. An animated discussion on the subject of the relation of human and bovine tuberculosis took place, and the conclusion was arrived at that no precautions should be relaxed to safeguard human beings against any possible contagion. A resolution put by Sir Patrick Manson urging all Governments to take steps to recognize the mosquito malarial theory, and to enforce its adoption, was carried. A discussion on the plague was held, and a resolution was passed that the conditions of quarantine against the disease should be improved. The next congress will meet in Berlin in 1907.

**Spitters Punished.**—On one day last week the New York City sanitary officers who had been detailed to look for violations of the anti-spitting law arrested eight men for expectorating on the platforms of the elevated stations as well as on the floors of the elevated cars. Four of the delinquents were fined from one to three dollars each.

**School Children Excluded for Medical Reasons.**—As a result of the medical inpection of children of the public schools in this city, on the opening day last week, one hundred children have been excluded from the schools by order of the Board of Health. Of these thirty-five were suffering from trachoma, sixteen from conjunctivitis, fifteen from parasitic diseases, three from skin diseases, and one from tonsillitis. They are under the care of nurses provided by the city.

**Nazarene Nurses.**—A Catholic women's association in Brooklyn has organized a class for what they term "Nazarene nurses," which began last Monday to train mission workers to care for the sick poor of Greater New York. This course is not intended to produce registered trained nurses, but merely to teach the rudiments of the art of caring for the sick in order that the settlement workers and missionary assistants may be enabled to aid the physicians in their work among the destitute sick. The course will comprise ten weeks of study.

**For the Reëstablishment of the Army Canteen.**—Brig.-Gen. Frank D. Baldwin, commanding the Department of the Colorado, in his annual report urges the reëstablishment of the army canteen under proper restrictions. He says: "I have been deeply impressed by the very marked differ-

ence in discipline and general contentment among the enlisted men since the abolition of the canteen feature of the post exchange. If men are unable to get a glass of beer in a decent and orderly manner in the garrison, they will resort to the vile brothels which cluster around the borders of the reservation, where they drink all manner of alcoholic beverages and often sink into debauchery and ruin." Gen. Frederick D. Grant of the Department of Texas has also borne testimony to the same fact in his annual report, from which we quoted in a recent issue.

**Dr. Morris Bailey** of Titusville, Pa., lately celebated his eighty-fifth birthday, says the *New York Times*, and especially marked the day by erasing from his books accounts extending over half a century and aggregating about $42,000. He still has some $10,000 "hard to collect" accounts, and may some day settle these in the same way. But paying patients, we are pleased to learn, have supplied him with a competency.

**Gift to an Eye and Ear Infirmary.**—The Newark Charitable Eye and Ear Infirmary is to have new quarters in a building to be erected on Central avenue, between Washington and Plane streets. The infirmary association has purchased the land, and one of its members, who will not permit his name to be made public, has given $50,000 toward the erection of a fireproof building, for which plans have been made.

**Disease in the Philippines.**—One hundred cases of bubonic plague were recently reported in Tondo, the most northern and most populous suburban district of Manila. Of these, eighty had a fatal termination. Twelve cases, with nine deaths, have also been reported from Cebu, in the Province of Visayas. Cholera is prevalent in all parts of the island as the result of an absence of rain.

**Experiments with Food Preservatives.**—Announcement is made of an early resumption of the experiments to determine the effect of various so-called food preservatives upon the human system, which Dr. Wiley, chief chemist of the Department of Agriculture, conducted for several months last winter. The general character of the experiments will be the same as last year. The official report of the experiments conducted from last November until June by Dr. Wiley is now in the hands of Secretary Wilson, but will not be made public until the entire series of experiments is completed.

**A Strenuous Turkish Doctor.**—Dr. Djeved Abdullah Bey, the physician to the Turkish Embassy in Vienna, recently thrashed the Turkish Ambassador, Nedim Bey, whom he accused of sending unfavorable reports concerning him (Djeved) to the Porte, thereby preventing him from securing a better position. The assault took place in the Turkish Embassy in the presence of the Secretaries and a visitor. Dr. Djeved was summarily dismissed, and the bruises which he had inflicted were dressed by a giaour surgeon of the vicinity.

**Bequests to Hospitals.**—The will of the late Dr. Joseph Schnetter, who died last month in Germany, sets aside $40,000, the interest of which is to be paid as an annuity to a family servant. At her death $25,000 of the fund is to go to the German Hospital and $15,000 to Mount Sinai Hospital, to endow beds for women.

**A New Peril in Matrimony.**—A woman physician was arraigned recently in a police court charged with practising medicine without being registered. She produced in court a copy of her registration under her maiden name, and said that when she was married three years ago she did not know that it was necessary to register again under the new name. The magistrate dismissed the complaint, but advised the physician to lose no time in securing a certificate of registration under her married name.

**Cholera in Syria.**—Cholera is reported raging fiercely at Birejik, Syria, a town of 10,000 inhabitants on the left bank of the Euphrates, at the head of navigation.

**A Conflict of Authority in Chicago.**—The Health Commissioner of Chicago is moved to indignation by the action of the Superintendent of Compulsory Education of the School Board in organizing an "emergency corps" to deal with diphtheria among the children of the public schools. In a recent Bulletin of the Health Department, the "physicians of Chicago, school principals and teachers and parents of school children are officially notified that they are not required, either by State law or city ordinance, to report cases of contagious disease, suspected or actual, to any authority except the Contagious Diseases Division of the City Health Department." The Health Commissioner explains that "this public notice is made necessary by a renewal of the efforts of the Superintendent of Compulsory Education of the School Board to operate an independent health department of his own. His motive is no doubt a laudable one, and if his efforts were guided by a moderate degree of professional intelligence and qualification for the work they might be beneficial instead of detrimental. As it is, they are meddlesome, mischievous, and sensational."

**A Tuberculosis Farm in Colorado.**—On May 21 there was formally opened, about five miles from Denver, what is to be called "The Denver Association Health Farm," the aim of which is to provide a sanitary home with nutritious food and pleasant occupation for persons of small means who are in need of the restorative influence of the Colorado climate. The Association Farm consists of ninety-four acres—a thirty-four acre fruit farm, the gift of Mr. and Mrs. David Brothers, and a sixty acre ranch. The present equipment includes a brick house for office, superintendent's residence, parlor, dining room, kitchens, cellars for one thousand barrels of apples, stable, and a group of cottage tents for the guests of the farm. Only one resident will occupy each tent. The first contribution (of $5.00) to the farm fund was made by Dr. Edward P. George of Hanover, Germany.

**Strange Action of the Alabama Legislature.**—On September 17 a resolution was passed unanimously by both houses of the legislature of Alabama naming the late Dr. Jabez L. M. Curry as one of the two men to represent Alabama in Statuary Hall, in the National Capitol. On the following day the Senate reconsidered this resolution by a vote of 20 to 8, and the House, by a vote of 43 to 11, with similar action. No explanation of this sudden change of mind was given in the press despatches recording the reversal of opinion.

**The Late Dr. Robert Newman.**—At a special meeting of the Faculty of the New York School of Physical Therapeutics, held September 14, 1903, the following resolutions were adopted:

"*Whereas*, Time in his unswerving course, has removed from our midst an associate, knowledge of whom engendered not only respect for his honesty of purpose and indomitable courage of conviction, but personal affection because of the uniform kindly courtesy of his deportment, Therefore be it

"*Resolved*, That the sympathies and condolences of the members of the Faculty of the New York School of Physical Therapeutics, be, and hereby are,

extended to the bereaved family of the late Dr. Robert Newman, and that, in token of the esteem in which they hold his memory, the secretary be instructed to forward a copy of this resolution to his family."

CLARENCE EDWARD SKINNER, M.D.,
President of the Faculty.

HERMANN GRAD, M.D.,
Secretary of the Faculty.

**Obituary Notes.**—Dr. EGBERT GUERNSEY of this city died of bronchopneumonia at his summer home in Fishkill Landing, N. Y., on September 19. He was born at Litchfield, Conn., on July 3, 1823. After passing through Phillips Academy at Andover, Mass., and the Sheffield Scientific School of Yale University, he came to New York and studied under Valentine Mott, receiving his degree from the Medical Department of the New York University in 1846. At first he combined newspaper work with medical practice, and was for a time editor of the *Evening Mirror*, being later one of the founders of the *Brooklyn Times*, of which he was editor for two years, and at the same time city physician of Williamsburg. Dr. Guernsey was a man of strong convictions, and suffered at times through the expression of them. He became a believer in homœopathy, and joined that body, through which action his membership in the regular societies was forfeited. Later in life he strove to broaden the rules of homœopathic practice, and to reconcile the differences of his school with the principles of regular medicine. For this he was expelled from the New York County Homœopathic Medical Society, but was reinstated by the unanimous vote of the members a few years later. Dr. Guernsey was for six years a professor in the New York Homœopathic Medical College, and was one of the founders of the Western Dispensary and the Good Samaritan Hospital and a member of the Staff of the Hahnemann Hospital. He was instrumental in having the inebriate asylum on Ward's Island converted into a general hospital, under the Charities Department, and was one of the originators of the State Hospital for the Insane at Middletown. In 1872 he founded the New York *Medical Times*, of which he has always been the senior editor.

Dr. S. S. H. STOUT died September 18 in Clarendon, Tex., at the age of eighty-two years. He was a native of Tennessee. He served through the war between the States as director of the medical department of the Confederate Army. He was conceded to be the best Latin scholar in Texas. At the graduation exercises of Dallas University last spring he conferred the degrees on the graduates, and made an address entirely in Latin. Dr. Stout was graduated in arts from the University of Nashville in 1842, and in medicine from the University of Pennsylvania in 1848.

Dr. SIDNEY A. CAMPBELL died at West Pittston, Pa., on September 12 at the age of eighty-three years. He was a graduate of Jefferson Medical College in the class of 1849.

Dr. ELY E. JOSSELYN, physician to the Women's Department of the Pennsylvania Hospital for the Insane, died suddenly at Philadelphia on September 13, at the age of fifty-seven years. He was a graduate of the Medical Department of the New York University in 1873, and had been connected with the Pennsylvania Hospital for more than fifteen years.

Dr. J. BECHTEL MINTZER died in Philadelphia on September 18 at the age of forty-nine years. He was graduated from the Medico-Chirurgical College in 1884.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

THE WAR COMMISSION'S REPORT—VINDICATION OF ARMY MEDICAL DEPARTMENT—LIVERPOOL TROPICAL SCHOOL—ANOTHER EXPEDITION—BRUSSELS CONGRESS—TUBERCULOSIS STATISTICS—THE LATE H. G. CROLY AND DR. SMILES—DISAPPEARANCE OF MISS HICKMAN.

LONDON, September 4, 1903.

THE medical department of the army has good reason to feel satisfied with the report of the Royal Commission on the South-African War. In fact, so far as I can see no other department can compare with it. This report consists of three bulky blue books, over 1,200 pages, and much of it goes to show the inefficiency rampant. In the evidence before the commission I notice that generals and others contradict each other on many points, one of them even, who achieved no distinction himself, going so far as to describe his superior's evidence on some points as "absolutely untrue," and saying some of his statements are "those of a man in a dream."

But my business is not with military matters, and I return to the medical department. This department saw no reason to reopen the inquiry made by that of 1900 into the department, but it brings into prominence the disgraceful fact that the provision made for the medical service was insufficient in time of peace, and yet was expected to suffice for a war. In fact, as Surgeon-General Sir W. Wilson testified, he had not a sufficient number of medical officers supplied for 80,000 men, and they had to take charge of 250,000, scattered over half a continent. Between the War Office and the Treasury lies the terrible responsibility. Lord Roberts testified that the medical service is under greater disabilities than the other departments; it was not prepared for expansion, "but was called upon to provide, within a few months, officers, non-commissioned officers, orderlies, and nurses for an army three or four times the size of that for which its establishment had been estimated as sufficient." Lord Roberts further remarked that but for the outbreak of an epidemic the department might have proved equal to the occasion. But he told the commission that such an outbreak is inevitable in war, and the failure which occurred for a time was not due to inefficiency or want of zeal in the medical men, but to the arduous nature of the military operations and the impossibility of giving precedence to medical supplies on the railway.

With this vindication the medical service may well be content. That it never had a chance of doing more must, as I have said, be charged to the military officials who have for years starved the service so systematically that the medical journals have over and over again predicted just what has occurred. Mr. Broderick has certainly signalized his administration of the War Office by a degree of justice to the medical service which is already bearing good fruit. But that even so energetic a minister will be able to cleanse the augean stable is doubtful, seeing that General Sir R. Butler told the commission plainly that nothing worth doing would be accomplished until "the War Office was abolished as it stands." Sir Redvers gave them a characteristic illustration to this effect. At Ladysmith, by sweeping the colony with telegrams for beds for the hospital, some van loads were obtained and he saw them arrive, but going to the hospital on that day week the sick were still lying on the floor. On investigation he found that the whole week had been consumed by two departments in disputing which should take them on their books and deliver them, while the doctors remained helpless and in despair. So much for red tape. Much more Sir Redvers told about war office management, and when we remember that he had twenty-five years' experience of it, he will be able to criticise its methods. Like every other witness who was asked, he gave flattering testimony to the zeal and energy of the medical officers.

The twelfth expedition of the Liverpool School of Tropical Medicine sails to-day for the Congo. The king of the Belgians contributes to this as the sovereign of the Free State. I feel special interest in this expedition, as I have several friends in Congoland, some of whom will be pleased to assist so far as they may be able. A letter from one recently received states that sleeping-sickness is quite epidemic in some parts. He lately passed through villages which had been desolated by it, but which, two years ago, when he visited them, were free from the disease.

At the Brussels Congress, now sitting, I hear that Drs. Brouardel and Mosny of Paris have a paper in which they commend the example of England *re* Tuberculosis to the French and other governments. In a report by these physicians are the following statistics of the mortality from phthisis in different countries per 10,000 inhabitants: England 13, Belgium, Sweden and Norway 17, Holland

and Italy 18, Switzerland, Denmark and Ireland, 20, Germany 22, France 30, Austria 36, Russia 40. These figures are for the year 1899. From the same correspondent I learn that the French legislature has appointed a committee to visit the sanatoria of Belgium and Germany and compare them with those in France, and that this committee will begin its tour to-day.

Dublin has lost one of her leading surgeons by the death, on the 28th ult., of Mr. H. G. Croly, who had been elected twice successively President of the Royal College of Surgeons in Ireland. He took the F.R.C.S.I. in 1863, and the M.R.C.P. in 1881. At an early stage of his career he taught anatomy at the college school and was elected surgeon to the City of Dublin Hospital. He was a brilliant operator. He kept abreast of the progress of surgery generally, was one of the first to accept the antiseptic system, a constant contributor to the surgical and pathological societies and to the Academy of Medicine after its establishment. He will be much missed at these meetings. He was a J. P. for the country.

Dr. Wm. Smiles died on the 26th ult., aged eighty-seven. He had been retired for some years. He was formerly surgeon to H. M. Prisons, and Physician to St. Pancras Dispensary. He took his M.D. at Edinburgh in 1839, his M.R.C.S. in England in 1861. He had served as V.P. at the Medical Society, and was a corresponding member of the Madrid Academy.

Much excitement has been fomented by the newspapers respecting the mysterious disappearance of Miss Hickman, M.D., who left the Royal Free Hospital the day she arrived to take charge for the house surgeon, and has not been heard of since. Numerous are the guesses made, but there are no facts in favor of any. One naturally thinks of the cases of automatic wandering, but I do not remember of a recorded case lasting so long, for Miss Hickman has been missing above a fortnight.

---

## LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

OVERCROWDING IN MANILA—UNHYGIENIC HABITS OF THE CHINESE—THE RIVER POPULATION—CONTROL OF DANGEROUS TRADES—OFFENSIVE TRADES—GRADUAL INCREASE OF SANITARY KNOWLEDGE AMONG THE FILIPINOS

MANILA, August 1, 1903.

AMONG the factors unfavorably affecting the health conditions of Manila, the matter of overcrowding is one of the most important. This condition exists in a dual sense, not only as overcrowding within buildings, but in the crowding together of the buildings within the city on a too restricted area.

The too great crowding together of buildings is the direct result of present totally inadequate means of transportation about the city; it being necessary for the poor classes, whose means are insufficient for the keeping of a horse and carriage or a daily expenditure for carriage hire, to live within a reasonable distance of the place of their employment. In this climate the performance of a fair day's work at heavy labor, in addition to the fatigue of walking any long distance to and fro from the place of employment is not practicable, and in meeting this demand for house space near the center of the city the owners of ground have permitted the latter to be built up far more closely than is compatible with the interests of the public health, and with a greatly increased danger of widely destructive conflagration. At present nothing can be done to remedy this condition, as rents are high, and the number of houses in the city is not sufficient properly to shelter the population. An early improvement may be expected however, when the electric street-car system, the franchise for which has been granted, and the work on which has been inaugurated, shall have been completed. This street-car system, extending to every portion of the city, will render life in the suburbs much more comfortable and economical for the poorer classes, and will enable any place of employment to be reached in a few minutes from any part of the city. As soon as this street-car system is finished, the work of gradually removing the more insanitary habitations from the too congested districts should be begun, and rational sanitary requirements as to a reasonable amount of building space insisted upon. At present, with inflammable and insanitary buildings packed together as they are in some districts, there are too great facilities at hand for widespread destruction of property by fire and the transmission of infectious epidemic disease from house to house.

Overcrowding within habitations assumes a somewhat different sanitary importance, according as this overcrowding occurs in Filipino houses of loose construction and light materials, or in the buildings of solid masonry erected according to Spanish ideas. As the former type of house is built well above the ground on bamboo posts, and there is always ample movement of air currents through the open spaces in the walls and bamboo floor, these houses are always dry, and are ventilated to such an extent that the inmates are practically in the open air. Fortunately, also, these native houses are small and capable of containing relatively few persons, and there is no opportunity to transform them into the barrack type of tenement building seen in low-class houses of solid materials. Overcrowding in these native bamboo and nipa houses affords opportunity for the transmission of communicable disease from one individual to another, but there is not present the influence of foul air, highly contaminated with human impurities, by which the vital resistance of the inmates of such a house is slowly overcome, and they are predisposed to acquire more readily any infectious disease with the germs of which they may come into contact. Further, the well-aired native house is less liable to harbor the germs of infectious disease, as these are constantly exposed to destruction by desiccating air currents and sunlight, and to removal from the habitation by falling through the spaces between the bamboo slats of the floor to the ground below. In houses of this type the matter of cubic air space has no sanitary importance, and the establishment of a minimum per capita floor space is all that is required; thus permitting no excessive number of persons to crowd together, limiting the spread of infectious disease should it break out among them and rendering its transmission to the small domestic groups in other houses less liable to occur.

Conditions quite different from the above obtain in the buildings of solid construction, particularly those of masonry, occupied by the poorer classes, and especially by the Chinese. In these buildings, which are frequently large, the floors of the basement rooms are usually of dirt, but little elevated above the outside ground level, and are foul and damp. Many of the rooms in such houses have no communication directly with the outer air, and can receive light and ventilation only through the door opening into an exterior room. Rooms which are insufficiently lighted are almost invariably found to be uncleanly, and in the presence of darkness, moisture, organic matter, and stagnant air the germs of the infectious diseases to be combated in Manila find conditions most favorable for their existence and development. As this class of houses is located chiefly in the more densely populated districts where rents are high, the poorer class of tenants is practically forced by financial necessity to crowd into dark, damp, and unventilated rooms of a capacity totally inadequate for their numbers. This state of things is highly undesirable, but the lessening of the condition of overcrowding is scarcely practicable until the electric street-car system renders the cheaper rents of more sanitary houses in the suburbs available for the laboring classes. The condition may then be expected to improve to a considerable extent among the Filipinos as a result of rapid transit, which must have a marked influence upon the laws of supply and demand. The Chinese, however, who particularly resort to these insanitary buildings of solid construction appear to have an instinctive tendency toward overcrowding, and to render this even more potent in its effects by carefully closing in, particularly at night when the greatest number of persons are present, even the few existing apertures by which ventilation might be partially accomplished. Without sanitary regulation they would in many cases crowd together under conditions rendering their habitations literally plague spots. Improved transportation facilities will have no effect upon the mode of life of this class of population, and hence the minimum permissible floor space and cubic air space, per capita, should be strictly defined to prevent the evils of overcrowding: The use of mezzanine floors and cubicles, as increasing the liability to overcrowding and intensifying the effects of this condition, should be strictly prohibited for sleeping purposes. At present the sanitary authorities are unable to enforce regulations for the prevention of overcrowding, as in the absence of sufficient houses to afford proper shelter any such action would work great hardship to the poorer classes.

No inconsiderable part of the population of Manila lives in houses which have no street frontage, and can be reached only through narrow alleys or by passing through another house. These houses are frequently mere makeshifts, built of refuse material and cannot be made sanitary in any way. Frequently the very worst specimens of these interior habitations are located behind buildings of good character occupied by a relatively high-grade class of tenants. These interior houses are a cause for much perplexity on the part of the sanitary authorities of the city. As the life of these flimsy habitations is only a few years, they are being condemned and removed as fast as they fall into decay, and rebuilding is either prohibited or else permitted only under such special

conditions as will permit of the carrying out of proper sanitary requirements. A necessary part of the future improvement of the city lies in the removal of these interior houses, which are unquestionably important agents in raising the death rate of Manila.

Questions of much sanitary importance are also raised by the residence of a large portion of the population of the city, probably aggregating some 15,000 souls, upon cascoes, lorchas, launches, and other small vessels plying in the river, esteros, lake, and along the water front. These people, men, women and children, permanently live on the boats upon which they are employed, and are with difficulty kept under proper sanitary supervision by reason of the constant movement of the water craft upon which they are resident. The pollution of the river and esteros by this floating population by excrement and refuse thrown therein, is impossible of prevention, nor can these people be restrained from using such polluted waters for purposes of drinking, cooking laundering, and bathing. A sufficient supply of good water for such purposes is never maintained aboard these boats, and even where an honest effort would be made by some individuals to secure good water for drinking and cooking it frequently happens that the casco or lorcha is made to seek temporary anchorage at parts of the water front and river where water from the city supply is practically unobtainable by reason of the great distance to the nearest pipe line or public fount. Under such conditions, if cholera occurs on board these water crafts and the river becomes infected, it is impossible that the disease should not prevail among this class to a far greater extent than among the rest of the city population. This has been true to a large extent of the cases that have occurred during the present calendar year, when repeated bacteriological tests have shown the sluggish reaches of the river to be infected with cholera; although at the same time the numerous water crafts of the Quartermaster's Department of the Army, which were required to procure and maintain a sufficient supply of distilled water from the military distilling plants had practically no cases of cholera develop on board, though otherwise under the same sanitary conditions. Not only is this large casco and boat population difficult to keep under sanitary control, but it is composed of a less intelligent class of people which chafes under any restrictions and evades them where practicable. Although contacts from cholera are no longer placed under quarantine, and the precautions usually taken consist merely of the removal of the sick and the disinfection of the boat, the latter operation is so distasteful to this boat population that the sick are usually hurried to some place ashore where they are later found by the inspectors; or if such removal was impracticable and the patient had died, the body was in many instances disposed of by being weighted and thrown at night into the river: a procedure which, among a people so imbued with the religious belief of the importance of burial in consecrated soil, shows their repugnance to even the simple sanitary precautions required. Whether the sick person was found on shore or the body was removed from the river, in almost no instance is it possible to ascertain the boat upon which the case of disease developed, and thus the sanitary authorities are unable to seek it out and destroy any infection aboard. Clearly the sanitary questions raised by the existence of this boat population are not readily to be solved To require its removal to the shore for residence would be impracticable, and to send the boats out into the bay for anchorage when not actually in use would be productive of much hardship, financial loss, and, in the case of sudden storm, serious disaster An important step in advance would be the erection of public latrines ashore close to the usual points of moorage, and to require the use of such public latrines. While this regulation would undoubtedly be broken at night, it could be enforced during the day time, and thus a large part of the water contamination prevented. An even more important sanitary step would be the piping of the city water supply to numerous places on the river front, where public founts would permit the boat population readily to procure a supply of pure water. It is easy to deplore the general use of river water by this class of the population, but until some other source of supply is provided for them they have no other recourse. This matter is of such importance that it should receive early attention by the municipal authorities—but there is so much to be accomplished in doing the numerous other new things that ought to be done, and rectifying the sanitary mistakes evident in practically everything done by the Spaniards, that this improvement will have to take its turn among other necessary reforms.

The question of the proper restriction and control of offensive and dangerous trades is also one of far-reaching sanitary importance for the city of Manila. The present law prohibits the establishment of any new business of an offensive or dangerous nature within the district of strong materials, or the maintenance of any such business not conducted in a sanitary manner. In the absence of proper sewerage facilities, the waste from such establishments as breweries, tanneries, dye-houses, etc., in the city necessarily drains into the esteros and largely contributes to their pollution and offensive condition. Even those establishments of this character located outside the district of strong materials, discharge their wastes largely into the heads of esteros, through which they are conveyed into the heart of the city and become a cause of great nuisance—thus practically nullifying the sanitary advantage of removing such establishments from the more densely populated sections of the city. The situation can only be satisfactorily dealt with by the enactment of a law prohibiting the future location of any establishment for the conduction of an offensive trade at any point within the corporate limits of the city, or upon any estero the waters of which flow within the city limits and by requiring also that all establishments now in operation for the conduction of offensive trades, located within the city limits or discharging wastes into an estero flowing therein, shall be removed within five years, or such other period as may appear to be reasonable. The early enactment of such a law will ultimately result in less interference with business interests as new establishments of the above sort are, from time to time, being put into operation in localities from which there is no question but that the sanitation of the city will require that they should be removed in the future.

A law prohibiting the occupancy for kitchen and dormitory purposes, of buildings in which offensive trades are conducted, is also much needed. At present a large part of the workmen engaged in offensive trades, particularly Chinese workmen, live, eat, and sleep in such buildings among highly unhealthful surroundings, and when cases of cholera or plague occur in such establishments it is often almost impossible to secure proper disinfection.

Another great factor influencing mortality rates in the Philippines is the unsanitary personal habits of a large part of the population. These habits are, to a certain extent, the result of racial customs and to the attainment of a less high degree of civilization, but it is no less true that they are dependent in considerable degree upon conditions of environment. The sovereignty existing in these islands prior to American occupation apparently concerned itself but little with the sanitary welfare of the people, and while much in the way of reform has been accomplished since 1898, the fact remains that certain improvements essential to the public health, even in Manila, have not yet been introduced. As the public welfare must be safeguarded by certain restrictions applied to the individual, so the individual has a right to expect that the governing authorities will in turn provide him with certain sanitary conveniences, by means of which he may live in greater comfort, and the resulting improvement of his mode of life and surroundings may redound to the health and well-being of his community. Thus in the city of Manila, in the absence of a pure, abundant, and properly distributed piped water supply and of a satisfactory system of sewerage and of sewage disposal, it is quite impossible for the poorer classes to conform to the most modern sanitary requirements, and certain important regulations—as, for instance, the prevention of the pollution of the esteros, or the proper disposal of excreta—cannot be satisfactorily enforced, because of failure by the authorities up to the present time to provide proper facilities for the disposal of wastes. With the vast amount of work of improvement required to be done about the city, it has naturally been impossible to accomplish everything during the short time and with the limited funds available since the American occupation, but under present more settled conditions the importance of at once securing certain sanitary essentials should commend itself to immediate attention. It is at present impossible to prevent a number of customs of the lower class of people, which have a marked influence in increasing the mortality, in the absence of various fundamental sanitary conveniences and necessities.

It must not be considered, however, that the habits of the people have undergone no improvement during the period of American occupation, for the reverse is quite the case, and especially in Manila there has been a marked change for the better, in this respect, as sanitary conditions through the city have been gradually improved. This change has been brought about by personal example instruction by government officials, and by the general enforcements of sanitary regulations, a task rendered much easier through the apprehension excited by the outbreak of cholera. Even with the gradual relaxation of previously compulsory sanitary requirements, the

poorer classes have not wholly returned to previous unhygienic practices, and the value of cleanliness of person and environment and the use of pure water is at present far better realized than was the case eighteen months ago. Of course, racial habits and customs established by generations of usage cannot be immediately done away with even under the best conditions; but it is possible gradually to modify and improve them, and this has already been accomplished in no small degree. Of course the best results must be looked for in this respect from education of the younger generation, whose habits are not yet thoroughly established. and to this end instruction should be given in all schools with respect to the elementary principles of personal hygiene, house sanitation. and the causes and measures for the prevention of transmissible disease. Immediate and radical change in habits of life cannot be expected of the older people, and the sanitary regeneration of the Philippines must be planned for the future through impressing the present school children with the necessity for living under more sanitary conditions and giving them instruction as to the best methods by which these can be brought about

## LETTER FROM NEW ZEALAND.

(From Our Special Correspondent.)

A MEDICAL PRACTICE BILL—MANAGEMENT OF INFECTIOUS DISEASES—A SMALLPOX HOSPITAL—CONTAGION IN BANK BILLS—PYLORECTOMY—DECREASING BIRTH RATE AND LOWERED DEATH RATE—PLAGUE.

AUCKLAND, August 20, 1903.

THE profession here, represented by a branch of the British Medical Association, has promoted a bill which is now before our Parliament for altering the conditions upon which foreign and colonial degrees can be registered. so as to qualify the holders for practice in New Zealand. The regulations of the Medical Council of the United Kingdom require. as you are probably aware, a curriculum extending over five years, and an examination on general subjects previous to commencing the purely medical studies Most, if not all, of the institutions for granting degrees in the British Empire have regulated their curricula in accordance with the requirements of the Medical Council. Some of the universities or other institutions granting medical or surgical degrees in the United States formerly allowed their students to go up for examination after a course of study of three or even two years. Practically we find that druggists, herbalists, and various quacks, who want to become registered medical practitioners in New Zealand, go over to the United States and come back in a couple of years with the title of M.D. This we are determined to put a stop to if possible. The bill provides that no medical degrees or titles shall be registered here unless a course of at least five years' study at a recognized medical school or university has been undergone. In the discussion on the bill one of the speakers informed the House that there would be no objection to the degrees granted by Harvard! I hope Harvard graduates will not be attacked by megalomania when they learn that New Zealand will recognize their degrees.

I observe that this question is exciting considerable attention in the United States. It certainly is very desirable that a uniform curriculum should be required in all the States. Unfortunately in New Zealand, where we have no large towns, the local hospitals do not afford sufficient material for clinical study. The plan in vogue now of whirling off every infectious case to isolation hospitals renders it impossible for an ordinary student to learn practically the symptoms, pathology, and treatment of such diseases as scarlatina, diphtheria, measles, erysipelas, or even typhoid fever. To us of the old school all this excessive fuss about infectious diseases seems very absurd. It is not to save the other medical cases that such separation is required, but to safeguard the laparotomies and the complicated operations. The proper way to do this is to have a separate staff and separate buildings for the surgical cases.

We are now in the vortex of a furious storm about the locality of a hospital for smallpox cases. This disease has established itself in Tasmania (an island to the south of the Australian continent), which is the last port of call for certain steamers coming to New Zealand. About seventy or eighty cases have occurred at Launceston, Tasmania, and a fair proportion of deaths. Of course all steamers coming from there are quarantined, but those coming from other ports (Hobart) in the island are allowed to land passengers and goods after examination and a very inefficient disinfection. If the disease comes no other way it will come by letters and newspapers. I had a newspaper from Tasmania delivered at my house the other day by mistake. I instantly went into the kitchen and put it into the oven, where it was baked for an hour. When I was Medical Officer of Health of a West Indian Island and variola made its appearance, I revaccinated all the officials of the Colonial Bank. All the cases were successful, with a good deal of constitutional reaction, and only two of the staff caught smallpox. These two were the teller at the counter and one of the officers who checked him and had to handle the notes. I had expressly cautioned the manager to allow as few of the staff to touch the notes as he could manage with. Dirty notes were burnt.

An operation of pylorectomy by Kocher's method, was performed here four weeks ago by Mr. Hope Lewis, one of the surgeons of the Auckland Hospital, in which about one-third of the stomach was removed and the portion of the duodenum involved in the cancerous growth. The man has made an uninterrupted recovery. He took slops on the fourth day, and in nine days took minced chicken; on the fourteenth poached eggs on toast. He sat up by the fire on the eighteenth day, and is now alive and very well, walking about the ward, etc., at the end of four weeks. He is putting on weight. Bowels acting well. The absence of pain since the operation is somewhat remarkable.

Mr. Hope Lewis is remarkably successful with all his abdominal operations, of which he has a great number.

The constant diminution of the birth rate is causing some uneasiness and a good deal of discussion. One sapient person recommends that women with large families should be granted a medal or some similar decoration! Another proposes that the fathers of six children should be allowed a preference in selecting land. One aspect of the question escapes notice, and that is the extremely low rate of mortality among children even in towns, but especially in country districts. It is better to have a low birth rate and a small death rate than a high birth rate and a mortality such as we used to have in England. I remember a huge Irishwoman bringing me a baby which she said was her thirteenth child, and she was uneasy about it because all the others had died! I said: "Do you mean to tell me that you have lost twelve children?" "Yes." "Then you ought to have been hanged years ago," was my unsympathetic reply. I found that the deaths were all owing to her preposterous system of feeding, and to stuffing three or four into one small room at night

We have had a plague case in Auckland, but very few people knew about it, and there were no hysterics about it. The man recovered. I believe more than half the deaths from plague are caused by sheer panic. Any one who has seen cholera or smallpox epidemics must have seen numbers of deaths from fright. This is particularly the case with the colored races. Negroes in the West Indies have been known to die of cholera in half an hour.

## Progress of Medical Science.

*The Boston Medical and Surgical Journal, Sept.* 17, 1903.

**The Dietary Treatment of Constipation.**—Henry F. Hewes has made a careful study of this subject. He first aims to learn the source or underlying cause of the trouble: next the method or methods of treatment of the condition in its various manifestations which will tend to establish the natural physiological function as far as possible as a permanent and self-supporting condition. Either the patient has some definite pathological lesion or condition, or he is living under a faulty condition of hygiene. Those hygienic factors which bear most directly upon the physiological function of the intestine are: (1) The habit of a regular period of defecation; (2) a proper amount of physical exercise; (3) a proper diet. In regard to the diet, it is necessary first to ascertain the exact nature of the patient's accustomed diet, and to supplement this until it corresponds to the normal diet. Foods, from the point of view of their influence upon intestinal action, may be divided into three classes: First, all food substances possessing a large or unabsorbed residue. These are chiefly vegetable substances having much cellulose, as the grains in coarse form, green vegetables, fruit, etc. Second, the foods containing considerable quantities of organic acids or other substances which increase intestinal activity, such as the tamarind, prune, plum, manna, and, certain green vegetables. Third, the substances which undergo fermentation in the intestine, with formation of organic acids. These are carbohydrates generally, including the cellulose of the vegetables already mentioned. In the treatment of constipation, then, having established the normal physiological diet for the patient, there is included in it a fair proportion of the above special forms of food. Besides general directions as to hygiene and health instructions are given to give up drugs and to depend entirely upon the diet. The writer then gives several tables illustrating diets helpful in this condition, and discusses their use. The results of his researches

show that in a very large majority of the cases of constipation, the chief if not the only cause or underlying condition is a failure of the patient to follow a normal physiological manner of life; also in a large majority a complete cure can be obtained by a proper direction of general régime and diet.

*Journal of the American Medical Association, Sept.* 9, 1903.

**Precision in the Determination of Human Parasites.**—A plea for this precision is made by H. B. Ward. He notes that the parasites are by no means all of etiologic rank; some are known to exert deleterious effects on the human organism, regarding the action of some much doubt exists, and there are others which are believed to be indifferent to man. Furthermore, even of those whose injurious effects are unquestioned, the results on the hosts differ notably, and the line of successful treatment differs equally. It is evidently important, then, to determine accurately with what species the practitioner has to deal in the individual instance. A mere diagnosis of "worms" is not consonant with the present-day requirements of medical science. Ward describes the various classes of parasites, their respective mode of entrance into the body and the symptoms caused thereby. Diagnosis necessarily implies the use of the microscope, yet it is simple, calling for no elaborate high-power apparatus. No cultures are necessary. We should examine the blood, sputum, urine, and fæces, though the three former rarely furnish evidence of infection.

**Uncinariasis in the South.**—C. A. Smith notes that this disease is found in the mountains as well as in the lowlands, increasing in prevalence as one goes toward the southern latitudes. It is not uncommon even in regions where the chance of contamination of drinking water by surface drainage is very slight. He finds that as a rule the eggs of the parasite do not hatch out in the bowel. Incubation seems to require mixture with earth, that is, air. Eggs are destroyed by freezing, as also by drying, but they must be thoroughly dry, the least bit of moisture preserving them. Fæces which are perfectly dry on the outside will be found to be moist in the interior and the eggs there still preserving their vitality. Smith believes that the parasite itself generally gains access to the body through the skin of the feet. Inoculation by drinking water is the exception. He describes the appearances of the ova, and symptoms produced by their development; instancing and presenting photographs of several cases. He does not consider it necessary to boil drinking water if the possibility of surface drainage contamination can be excluded. If every person will wear shoes which thoroughly protect the feet in rainy weather or in damp places, there is very little chance of infection.

To determine whether the parasite which infects the dog in his section would exist in the human body, Smith ministered successive doses of the larvæ of this parasite to a negro boy nineteen years of age (of course, with his consent), but results were negative, nothing being found in the stools.

*Medical News, September* 19, 1903.

**Chronic Nephritis without Albuminuria.**—Arthur R. Elliot, concludes: Latency of symptoms is so constant a characteristic of chronic interstitial nephritis as to almost constitute its most salient feature. Symptoms are especially liable to be absent and urinary signs uncertain during the early stages of this disease, consequently the diagnosis during this period must generally be made from physical signs rather than from symptoms or urinary signs. Albumin is absent from the urine of this form of nephritis with great frequency. Albuminuria constitutes a very unreliable diagnostic sign in this disease. More reliable evidence of renal change is diminution in the gross amount of urinary solids, and especially significant is the presence of casts. The secondary circulatory changes following chronic interstitial nephritis are so constant and characteristic as to furnish, in most cases, sufficient ground for the recognition of the disease before reference is made to the urine. The diagnosis of this disease should, if possible, be made from the physical signs and symptoms the urinary indications being regarded as corroborative rather than as essential evidence.

**The Modern Treatment of the Acute Suppurations of the Knee-joint.**—Arpad G. Gerster speaks of the acute purulent inflammations of the knee-joint under three heads: metastatic or pyemic suppuration; suppuration due to osteomyelitis; and traumatic suppuration. The onset of the metastatic form is generally mild, its course inclined to be chronic. If the local symptoms are troublesome they will demand surgical interference. First, evacuation by puncture, and if the collection be ropy and thick, by irrigation. Rapid reaccumulation will demand incision and drainage. The number of incisions must depend upon the acuteness of the local symptoms. One of the most troublesome forms of metastatic infection of the knee joint is that due to gonorrhœa. In suppuration due to osteomyelitis, the author recommends Mayo's incision. This consists of the transverse incision of the infected knee-joint, passing from condyle to condyle just above the patella, and, of course, dividing the quadriceps tendon. Ollier, the French surgeon, supplemented Mayo's incision by advising the extirpation of the crucial ligaments. The writer relates several cases of the third class. In one, Mayo's incision was used with very good results.

**What Ought We to Expect from Cardiac Drugs in Heart Weakness?**—O. T. Osborne describes a cardiac tonic as a drug that will more or less permanently strengthen the heart and pulse, and leave the heart in better condition after its action has ceased than it was in before. A cardiac stimulant, on the other hand, is a drug which will stimulate, and perhaps for a short time strengthen a weak heart, but when its action has ceased the heart is left really in poorer condition than before unless the cause of the weakness for which it was given has ceased to act. The principal cardiac tonic is digitalis, while the drugs which resemble digitalis in their action are strophanthus, sparteine, cactus, convallaria, adonidine, and last but not least, suprarenal preparations. Stimulating cardiac tonics are strychnine and caffeine, while the cardiac stimulants are alcohol, ammonia, camphor, nitrite of amyl, nitroglycerin, and ether. Digitalis should be used in broken compensation in valvular disease, in simple dilatation, in the irritable or weak heart of nicotine poisoning, in strained heart from overwork, over-athletic exercise, etc., also in cases of poor vasomotor tone, and when there is œdema or exudations with no serious kidney lesions. The action of digitalis in slowing the heart by its action on the pneumogastric nerve gives the heart a much-needed rest, and the action on the cardiac muscle making the contractions more effective and more complete, thus acts as regulated calisthenic exercise, and the cardiac muscle is increased in thickness and strength. The contraindications to the use of digitalis are a high tension of the arteries, atheroma, a weak cardiac muscle from prolonged fevers or from fatty degeneration, myocarditis, and, ordinarily, a serious kidney lesion. The best substitute for this drug is strophanthus. As a cerebral stimulant probably no drug equals caffeine. Coffee plus tobacco enables one to do an immense amount of brain work. If this is kept up long neurasthenia will supervene. The exact action of alcohol on the heart is not absolutely proved. Overdoses after absorption are depressant to the heart muscle, to the muscle of the blood-vessels, and to the vasomotor center in the medulla. To combat continuous or persistent cardiac failure or depression alcohol is the poorest stimulant that can be used, and if much is given the treatment is vicious. In serious feverish conditions undoubtedly the narcotic effect of alcohol may be of advantage in quieting the patient, as mental worry and anxiety are great disturbers of the heart and circulation, and should be overcome by any legitimate means.

*New York Medical Journal, September* 19, 1903.

**The Etiology and Treatment of Subacute and Chronic Catarrhal Affections of the Upper Air Passages in Children.**—J. A. Patterson discusses this question along conventional lines. Treatment should include cleanliness of the nasal passages, restoration of their normal lumen, and removal of tissue excess at any portion of the tonsillar ring.

**The Pathology and Treatment of Rheumatoid Arthritis.**—E. M. Menins states that a comprehensive definition of this affection includes the following inferences and facts: (1) The disease occurs in patients with an arthritic diathesis, or whose nervous system has been impaired by physical injury, shock, sorrow, or anxiety. (2) Its history and the general clinical aspect of the disease point to some form of chronic poisoning as being most concerned in its production, rather than to the direct action of a specific germ. (3) This chronic poisoning depends on the elaboration in the system of certain toxins, which apparently may be the product of any general infection or local morbid condition. (4) These toxins exert a peculiar and selective action upon the tissues of the joints and nervous system concurrently, and so produce the characteristic nervous phenomena and arthritis of the disease. (5) There is a small residue of cases closely resembling rheumatoid disease, if not identical with it, which seem to depend wholly and directly upon some functional or organic disorder of the nervous system, as so far they have not been traced, and perhaps cannot be, to any source of infection. Treatment should aim at the accomplishment of discovering and removing the source of infection, eliminating poison from the system, re-

pairing the damages done by the disease and relieving pain.

**Birth Palsies.**—M. H. Bochroch offers the following conclusions: (1) In a spontaneous labor, one should not (in making traction upon the head) be in too great haste to deliver the trunk. The latter should be left to Nature, or should be helped by means of expression. Only in cases of necessity should traction upon the head be made, and even then the head should be flexed laterally only so much as is absolutely necessary to conform to the necessity in the case. If it is found necessary to hook the axilla, too great traction should not be made. (2) During extraction by means of forceps, expression should be used as an assisting factor, presupposing that the shoulders meet with an obstacle at the entrance of the pelvis. One should remember Walcher's hanging position, and bring the forceps not far outside of the direction of the axis of the body. By this, however, is not meant that the slight pendulum movements sanctioned in textbooks should be omitted. Danger only arises when there is a deviation *from* thirty degrees, but a slight pendulum movement is not prohibited. (3) During extraction by means of the feet, the arms should be quickly attended to, in case they are interfering, by means of Mauriceau's procedure, *i.e.* by placing the finger in the mouth of the child and using the arm to assist in the traction, resorting in grave cases to expression, and, if necessary, to Walcher's position. If the extraction of the head offers considerable difficulties, this may be considered as an indication for the application of the forceps to the aftercoming head, in order to avoid stretching the nerves of the axilla. Under the head of treatment the author names massage, electricity, and if it shall appear that nerve-plexus have been torn, exposure of the latter and suturing.

*The Lancet, September* 12, 1903.

**The Treatment of Plague by Large Doses of Carbolic Acid Given Internally.**—The histories of six cases are given in detail by J. M. Atkinson. The treatment consisted in giving the acid in doses varying from twelve grains every two hours to six grains every four hours, according to severity of symptoms. Other remedies were administered to meet special indications. In one case over 2,500 grains were administered before the blood was free from the plague bacilli. The remedy was usually given in mixture, the dose being diminished on the supervention of carboluria.

**The Treatment of Cancer and Other Forms of Malignant Disease by Electric Osmose.**—The burden of the experiments by C. A. J. Wright is to show that the "radio-active salt of strontium introduced into the tissues or cataphoresis by high frequency" will prove the panacea of all forms of malignant disease. He has employed the remedy in twenty-three instances, in five of which it proved successful. Full notes of these cases are given, and he suggests that a recovery of 22 per cent. of all cases treated calls for a further trial of the plan by the profession at large. All the five cases were superficially situated—in fact, were of the class in which the *x*-ray has given such promising results. The paper opens with an illustrated description of the apparatus used and with remarks on the phenomena of electric osmose, and must be consulted in the original by those interested.

**Upon the Virulence of the Bacillus of Bovine and Human Tuberculosis for Monkeys.**—From an elaborate series of experiments by A. Macfayden, the following results may be noted: The monkey proved susceptible to an inoculation with the bacillus of bovine tuberculosis either directly or after one passage through the organism of the guinea-pig. A certain number of the animals died in two or in ten days after feeding with bovine and human tuberculous material. Normal human sputum did not produce this effect, and the result suggested some form of intoxication. The monkey fed thrice, twice, or once with the bovine material succumbed to a general tuberculosis in from one to two months, and fed with the human material the same results and fatal effect were produced in about the same period of time. A young monkey proved to be equally susceptible to the bovine and human strains of the tubercle bacilli. The striking difference in the effects produced occurred in the digestive tract. Intestinal lesions were found in the case of every monkey that had been fed with human tuberculous material, whilst none of the monkeys fed with the bovine material presented any evidence of tuberculous ulcers in the intestine. Within the limits of these experiments it would appear that virulent bovine tubercle bacilli may pass through the intestinal wall in large numbers without any detectable lesion of the gut being produced. It would also appear that a food tuberculosis can be as readily brought about by the bovine as by the human strain of the tubercle bacillus in the young monkey.

*British Medical Journal, September* 12, 1903.

**A Discussion on Miners' Phthisis.**—Thomas Oliver concludes that: Miners' phthisis is not the result of the inhalation of gases given off by the strata, nor evolved by the explosives used in mines. It is a disease in which there is a marked excess of fibrous tissue in the lungs, embedded in which can be seen numerous particles of coal dust and silicious material, in which also cavities may be seen and tubercle occasionally detected. It is a disease of occupation, due to the irritating action of dust, which renders the individual liable to repeated catarrh; it is non-tuberculous, not only in the early stages, but may even remain non-tuberculous throughout, when tubercle is present it is an accidental infection which, while hastening the end, does not exercise any very marked influence upon the pre-existing structural alterations caused by dust, unless it be a tendency toward disintegration. It is a local disease, purely personal to the individual, and never assuming hereditary characters. Accepting this view of the pathology of the disease, miners' phthisis, as experience in this country has shown, may be largely prevented by improved ventilation, and by the adoption of means for the removal of dust or for the allaying of dust by water.

**Discussion on the Pathology of Splenic Anæmia.**—H. D. Rolleston gives the clinical characteristics of this disease as: Splenic enlargement which cannot be correlated with any known cause. Absence of enlargement of the lymphatic glands. Anæmia of a type midway between secondary anæmia and chlorosis. Leukopenia, or at most, no increase in the number of white blood corpuscles. An extremely prolonged course lasting years. A tendency to periodic hemorrhages, especially from the gastrointestinal tract. This disease presents no characteristic blood picture by which a diagnosis can be made from a number of diseases which it more or less closely simulates. The spleen is enlarged in all directions and greatly increased in weight In some cases there is no change in the marrow of the long bones; in others, it has extended into the shafts of the long bones, as in pernicious anæmia. It is not yet known what cause produces the changes in the spleen. No microorganism can be correlated with the splenic change. The question as to whether the nature of the disease is an intoxication or an infection has not yet been fully answered.

**Case of Syphilitic Nephritis in an Infant Aged Fifteen Months.**—George Carpenter reports this case. He believes that catarrhal nephritis can arise from the action of syphilitic poison. This patient was the child of syphilitic parents. He presented all of the symptoms of nephritis. Necropsy revealed the kidney in a condition of catarrhal nephritis. Casts were visible here and there in the tubules. There were no interstitial changes. The small arteries in the neighborhood of the glomeruli were thickened and their lumens greatly diminished. The structural alterations in the blood vessels were probably responsible for the anuria which was a prominent feature in the case. The writer reports still another case of a child of five weeks, in which there was evidence of catarrhal nephritis in an incontestable syphilitic kidney The writer believes that congenital syphilis is capable of producing catarrhal nephritis as well as interstitial nephritis, and that there is no valid reason why one form should not occur independently of the other. This nephritis is indistinguishable clinically from acute catarrhal nephritis by reason of its symptoms, and its urinary deposits and interstitial kidney changes may or may not be present in such cases.

*Münchener medicinische Wochenschrift, September* 1, 1903.

**Intravesicular Separation of the Urine of Both Kidneys.**—Keydel considers the apparatuses which have been devised especially by Luys and Cathelin for the separation of the urine within the bladder in cases of catheterization of the ureters. The cases which have been reported are considered in detail, and it is shown that in the majority of cases the results have been satisfactory with the use of either instrument. Four of the author's own cases are given In three Luys' instrument was used, and in one Downe's. The results show that no one form of apparatus is to be universally recommended, but that each case must be handled upon its own individual basis.

**Absence of Casts in the Urine of Nephritics.**—Adolf Treutlein confirms the opinion that casts may be absent in cases of nephritis which show albuminuria and a typical retinitis albuminurica. This absence is not due to a digestive action upon the casts of pepsin, which may be excreted by the kidneys. Nor is it caused by the action of leucocytes which may be present in the bladder due to a coexisting cystitis and which may ascend to the urinary tubules of the kidney. Neither do the leucocytes

of surgical pus possess any such action. The destruction of the cylinder is caused by the action of the bacillus coli communis—but not by its ferments alone—which are present in the bladder or have invaded the upper urinary passages.

*Berliner klinische Wochenschrift, August* 31, 1903.

**Indications for the Induction of Labor in Hyperemesis and Cardiopathy.**—Oedön Tuszkai says that the diagnosis of hyperemesis gravidarum can only be made after careful exclusion by the employment of all diagnostic and therapeutic means. Especially should all hysterical influences be excluded. Even after the most rigid exclusion, the gravidity can only be regarded as the cause of the emesis when there is a local susceptibility of the uterus—that is, when a bimanual examination causes marked increase in the nausea or vomiting. Only in the latter class of cases should the induction of labor be considered, and here only after all local measures have been tried without avail, opium, in large doses has failed to give relief, and the life of the patient is threatened by inanition. Cardiopathy in pregnant women rarely calls for the induction of labor, nevertheless, its presence should be early detected in order that the patient should be carefully watched and serious consequences avoided. In normal individuals there is a marked difference in the pulse rate in the horizontal and upright positions. In cardiac hypertrophy and pregnancy when the heart is sound this difference vanishes. One of the first signs of cardiopathy in pregnant women is a return of this difference in the pulse rate. If during the beginning of the pregnancy the "pulse-difference" is present, it is, of course, a sign that from the inception of the same the heart has failed to compensate. All pregnant women should be frequently examined for the presence of this pulse symptom, in order that the conditions of the cardiac muscle may be accurately appreciated.

**Cytodiagnosis.**—B. Czerno-Schwarz and J. Bronstein review the literature relative to the value of cytodiagnosis in the examination of effusions of serous cavities in general, and give the results of their own studies respecting pleuritic exudates and the cerebrospinal fluid. Four cases of the former were examined and Courmont's and Arloing's views confirmed in that by cytological means as diagnosis cannot be made in cases of primary tuberculosis until the end of the second week of the disease. Widal and his school have claimed that it could be made earlier than this on account of the abundance of lymphocytes present in the fluid, but it is certain that previous to the time indicated polynuclear cells are abundantly present in tuberculous pleural exudates and render cytodiagnosis but of little, if any, value. Normally, the cerebrospinal fluid shows the presence of but few if any lymphocytes. This is also the case in the various neuroses, psychoses, diseases of the central and peripheral nervous system (excepting meningitis), brain tumors, and in the so-called meningismus. In progressive paralysis, the early stage of tabes, and meningomyelitis a lymphocytosis is present. In the early stage of tuberculous meningitis the polynuclear cells are in excess in the majority of cases; later on there is a lymphocytosis, but if secondary infections occur the polynuclears again become the more prominent. In epidemic cerebrospinal meningitis the polynuclears predominate, but in chronic cases, there is a lymphocytosis, except during exacerbations, when there occurs a polynuclear leucocytosis.

*Deutsche medicinische Wochenschrift, August* 27, 1903.

**Mechanical Treatment of Blepharoptosis.**—G. Abelsdorff has devised an apparatus for lifting the eyelid and completely relieving the deformity. The device takes essentially the form of a pair of eyeglasses. A slender gold wire which lifts the lid is concealed behind the upper margin of the frame on the affected side in such a manner that it cannot be observed when viewing the patient from the front. The glasses can be worn indefinitely without causing any significant irritation.

**Intermittent Hydrops Cured by Iodoform-Glycerin Injections.**—Wilsinger reports a case of intermittent hydrops of both knee-joints of thirty-five years' standing. Constitutional treatment had been tried in all forms without avail. The right joint had been "washed out" eight and the left six years previous. No recurrence had taken place upon the right side, but for some time past the fluid had recollected in the left joint at half-yearly intervals. A clear yellow serum was evacuated from this joint, and 10 c.c. of iodoform-glycerin injected. A pronounced local reaction was produced, which lasted for six days. Five months has now elapsed without recurrence, and there has been no interference with the normal functions of the joint. The etiology of the case is unknown. From this and the two similar cases which have been recorded it is probable that the disease is to be regarded as a local affection and closely related to synovitis.

**Antitoxic Tetanus Therapy.**—E. v. Behring states his theoretical views regarding the mode of action of tetanus antitoxin upon tetanus toxin, and gives his reasons for believing that the antitoxic molecule is united to the toxic by a third body, which he calls the "conductor." This body is derived from the substance of the axis cylinders and ability of any antitoxic serum to neutralize tetanus toxin in vitro depends upon the quantity of the "conductor" present in the serum. Moreover, this "conductor" outside of the body is very labile, and is easily broken down. Upon the basis of these views a new method of standardizing tetanus antitoxin has been evolved, and a serum thus standardized placed upon the market by Siebert and Ziegenbein in Marburg. The statistics of tetanus treated by antitoxin are reviewed, and the early and repeated use of large quantities in all cases of tetanus advocated.

*French and Italian Journals.*

**Kinesitherapeutic Treatment of Flat-foot.**—L. De Munter treats this affection as a muscular atrophy, applying energetic pétrissage with tapotement to the anterior and posterior tibial muscles, with resisted movements of adduction and supination of the foot, and effleurage of the tarsus. The ascending faradic current may be used in rebellious cases. Of course this form of treatment is of no value in old cases, or when paralysis is complete. The author has treated twenty-seven cases in this way, and has had fair success. He gives the statistics in full.—*Revue Internationale de Thérapie Physique*, August 15, 1903.

**Spinal Rheumatism.**—M. Jeanselme reports a case of this unusual form of rheumatic affection. The patient suddenly had pain in both feet, then in the knees, hips, and the *uretha*. Ten days later micturition was absolutely suppressed. There were no periarticular pains, but rather, painful spots along the course of the sciatic nerve. Under appropriate treatment the urine was voided and the following day micturition was normal, but the left elbow and leg were the seat of violent pain. The salicylate of soda brought complete relief. The alternation of meningomedullary symptoms with articular pains, and the rapid disappearance of both by means of the salicylate, justify the diagnosis of spinal rheumatism.—*Journal des Praticiens*, August 29, 1903.

**The Biological Action of Blue Electric Light on Muscular Labor.**—Raffaele Pisani concludes that the blue light increases the energy and resistance of the muscles. This is the case whether the rays be turned on the muscles while they are at work, or previous to their activity, but is more marked in the latter event. This favorable action is not always in proportion to the length of time to which the muscles are exposed to the blue light, but fifteen or twenty minutes exposure as a rule obtains the best results. The effects diminish in time. It is the blue light alone which has this action, white having no influence, and blue a depressing one.—*Annali di Elettricità Medica e Terapia Fisica*, August, 1903.

**Arthritism.**—Edmond Fiquet concludes from his researches that arthritism is not a disease properly so-called, but rather a predisposition to certain diseases, such as gout, diabetes, gravel, etc. It is the result of insufficient intracellular oxidation, and varies according to the nature of the oxidation process. If there be deficiency in the process which oxidizes the carbohydrates, glycosuric diabetes will appear; if in that which oxidizes fats, obesity will result, and if in that which should oxidize the albuminoid residue of nutrition, albuminoid diabetes will declare itself. Treatment is the same as in ordinary diabetes, except that albuminoids are to be forbidden in the diet instead of carbohydrates. Iron will increase oxidation, as will massage and hydrotheraphy by increasing cellular functions in general. Rest in the country is of value.—*La Presse Médicale*, August 22, 1903.

**The Treatment of Infantile Diarrhœa by Gelatin Solutions.**—E. Weill, A. Lumière, and M. Péhu claim to have had excellent results from the administration of this remedy. The gelatin must be as pure as can be obtained, and be subjected to a sterilizing process after making a 1 to 10 solution in boiled water. A gram of gelatin can be given with each feeding from the bottle, that is to say, 6 to 8 grams a day, or even more. Its effect is to diminish the number of stools, and cause them to become of a more normal type as to consistence, color, odor, and reaction. The general condition of the infant begins to improve after four or five doses. The authors state that this medication is of especial value in cases of simple gastroenteritis, but is, of course, of less use in digestive infections with high temperature, complicated by broncho-

pneumonia, congestive râles, spleno- and hepato-megaly and albuminuria.—*Lyon Médical*, August 23, 1903.

**Ehret's Disease.**—C. Pantaleoni considers this paralysis to be a functional one, but clearly distinct from hysterical paralysis, and constituting a morbid entity. It affects the peroneal muscles almost exclusively, and is nearly always accompanied by contraction of their antagonists. The cause is in the cortical centers, which for some unknown reason are less resistant in some persons than in others, and readily acquire habits which soon become permanent. Sometimes pain is a cause, or it may follow traumatism. The paralysis comes on slowly and progressively. Treatment should be directed toward training the cerebral centers by means of corrected position, and strengthening the muscles. If the disease be too far advanced to be affected by these measures, tender transplantation may be resorted to.—*Archivio di Ortopedia*, Vol. 20, No. 2, 1903.

**Adiposis Dolorosa.**—Paul Sainton and Jean Ferrand describe this affection, to which attention was first called by Dercum in 1888. It occurs as a rule in women over forty, pain in some limb being usually the first symptom, followed by the appearance of either limited or diffuse tumors of lipoma-like consistence. Asthenia accompanies these symptoms and ranges from slightly impaired muscular movements to an absolute refusal to leave the bed. Psychical troubles are also present in greater or less degree. The pathogenesis of the affection is not as yet well understood. As to treatment, extirpation of the nodular tumors has usually been followed by their reappearance; massage has given good results in some cases, possibly by improving the general condition. Internal medication has not been followed by any radical cures. Ewald was the first to try thyroid treatment, and his experiment was very successful, but other practitioners have had varying results with the remedy.—*Gazette des Hôpitaux*, August 22, 1903.

## Surgical Suggestions.

**Abortive Treatment of Boils.**—A 2-per-cent-carbolic-acid solution is used. A hypodermic needle is inserted obliquely through the outer edge into the center and a quantity of the solution injected. The needle is then withdrawn and reinserted at another point of the periphery, etc., etc. The results are almost magical. The process of necrosis is arrested and the already dead tissue rapidly falls away.—A. BIDDER.

**Gauze Drains.**—Gauze drains left in wounds should not, as a rule, be removed until the fourth day, when the adhesions have liquefied and the gauze is easily removed. In the uterus gauze should never be left in more than twenty-four hours, owing to danger of sepsis.—*International Journal of Surgery.*

**To Preserve Rubber.**—Ten to twelve parts of water and one part of ammonia will preserve soft rubber any length of time. Dip rubber pipes, etc., in a glass jar filled with this solution. Use for your ammonia bottle a rubber stopper: it is better than a glass stopper.—*Toledo Medical and Surgical Reporter.*

**Corns.**—A ring of glycerin jelly is painted around the corn to form a raised rampart. A piece of salicylic acid plaster mull is cut to the size and shape of the ring and placed upon the corn. The whole is painted with glycerin jelly and wrapped in cotton wool.—UNNA.

**The Microscope.**—If the clinical history and naked-eye appearance on fresh section indicate that the growth is malignant, but under the microscope the growth appears innocent, I regard the growth as malignant. If the macroscopical appearances are innocent, but the microscopical appearances malignant, I regard the growth as innocent. In other words, when the clinical and microscopical appearances differ, I base my judgment upon clinical history and macroscopical appearance on fresh section because I have found them more reliable.—C. HAMILTON WHITEFORD.

**A Simple Method for the Removal of External Hemorrhoids Under Local Anæsthesia.**—Thos. Chas Martin, President of the American Proctologic Society (*Cleveland Medical Journal*,), uses two hypodermic syringes with the finest needles, having long oblique points. A $\frac{1}{10}$ of 1-per-cent. solution of eucaine is prepared in a physiological salt-solution, which is administered at a temperature of about 98° F. The integument in the proposed line of incision and the tissues beneath the base of the tumor should be rendered uniformly œdematous by the endermic injection. The oblique portion of the needle's point should be laid on the skin, which is drawn tense, and by a movement of the fingers only, the needle should be pushed steadily in till its mouth is buried in the integument. The piston is now pushed, and as the welt rises in advance of the needle's point, the needle should also be advanced in the plane of the integument. Before making the incision a row of continuous sutures should be placed in the infiltrated area around the growth, then cut and converted into interrupted sutures, to be tied after the tumor has been dissected away.

**An Oily Solution of Cocaine.**—It is claimed that if cocaine be administered in a solution made up of equal parts of almond and petroleum oils, the effect will be of much longer duration, though slower in making its appearance.—*The International Journal of Surgery.*

**Vaselin in Ozæna.**—Brindel recommends interstitial injections of vaselin with a fusing point of 60° C. into the lower turbinate bones in cases of ozæna. The atrophic rhinitis becomes hypertrophic and the ozæna disappears. The amount used is from 3 c.c. to 4 c.c. at each injection.—*La Presse Médicale.*

**Abortive Treatment of Boils.—**

℞ Icthyoli.....
Æther.....ää 12.0
Spir. vini gallici dil..... 14.0

M. S. Apply externally twice daily.—GLIKMAN.

The **Fundal Incision** in the cæsarean section has the following advantages: (1) The wound being higher, the chance of ventral hernia is less. (2) There is less bleeding. (3) The placenta is less often in the way, and therefore less frequently cut into. (4) Extraction of the child is rendered easier. (5) The lower segment of the uterus being uninvolved, the wound is more readily stitched.—KERR.

**Treatment of Squint.**—Treatment should begin as soon as the slightest deviation is noticed, and should consist in the maintenance of fixation by bandaging or atropinizing the better eye, and by correction of all refractive errors. The fusion faculty should then be educated, and when that is well developed if the deviation is not corrected operative measures should be undertaken to produce approximate parallelism of the axes, as little can be done with the fusion sense after the sixth year. This parallelism can be perfected and maintained by further fusion exercises. The amblyoscope is adapted for use in any degree of squint, and which overcomes suppression of the image by increasing the illumination, at the same time amusing the child.—*American Medicine.*

**Treatment of Stye.**—The lash is removed from the center of the inflammatory area. The swelling should be carefully touched with tincture of iodine or pure carbolic acid. Where there is any pus it should be released by a small incision. Warm applications will lessen the pain. A weak mercurial ointment will generally cause the disappearance of the remaining thickening of tissue. The diet should be regulated when there is reason to believe that the condition is due to general constitutional atony. —*International Clinics.*

**Bronchiectasis.**—A patient was recently presented by Putnam, in whom he had evacuated several bronchiectatic cavities which gave out a profuse malodorous discharge. The cavities were emptied by means of the Pacquelin cautery at a low red heat, after they had been located definitely by means of an aspirating needle which was retained in position as a guide during the subsequent procedures. The wound healed nicely and without complications, and there has been no recurrence for more than a year.

# Book Reviews.

CANCER, ITS CAUSATION AND ITS CURABILITY WITHOUT OPERATION. By ROBERT BELL, M.D., Glas., F.F.P.S., Consulting Physician to the Glasgow Hospital for Women. London: Baillière, Tindall and Cox, 1903.

THE writer of this book is a firm believer in the curability of cancer, especially of epithelioma and scirrhus, if only treatment is begun early enough. He insists especially upon this point, and one of the avowed objects of his work is to urge upon the profession the importance of an early diagnosis and timely treatment and to encourage a campaign of education in these matters for the laity. Epithelial cancer, he holds, is a sort of running amuck of the normal cell (we are giving the author's ideas, not his words) which becomes altered in character, devours its neighbors, and reproduces itself with great rapidity, thus gradually destroying the healthy cells, replacing them by its own ungovernable progeny. In the great majority of cases the exciting cause of this malignant metamorphosis is trauma, but a predisposing cause must exist in a lowered vital resistance caused by autointoxication, worry, unhygienic surroundings, and especially the so-called 'uricacidæmia." The main treatment which Dr. Bell advises is the use of thyroid-gland extract combined, if need be, with the salicylates. Whatever we may think of the author's theories, there can be no doubt of the earnestness of his advocacy of them. The book must be regarded as a valuable contribution to the rapidly growing literature of cancer.

PORTFOLIO OF DERMOCHROMES. By Professor JACOBI of Freiburg im Breisgau. English Adaptation of Text by J. J. PRINGLE, M.B., F.R.C.P., Physician to the Department of Diseases of the Skin at the Middlesex Hospital, London. Vol. I. Parts 1 and 2. London and New York: Rebman Company, 1903.

THIS is a work intended primarily for the general practitioner, and for this reason the rarer forms of skin disease have not been selected for illustration, but rather those most frequently met with in ordinary practice. In this volume there are forty-two plates with seventy-eight separate figures. The plates, except some illustrating smallpox, are taken from models in Neisser's Clinic at Breslau. The process employed in their production is that known as "citochromy," the invention of Dr. Albert of Munich. The coloring is wonderfully clear, and in many of the pictures is most faithful, though, as is almost inevitable in the depiction of skin diseases, it is sometimes too bright The text accompanying the plates is brief, but yet not so condensed as to eliminate any of the essential points in the description of the disease. In short, the work is excellently adapted to the uses of the non-specialist or the student who has not the time or the opportunity to go exhaustively into the study of this most interesting branch of medicine. The work will be completed in two volumes.

SIGHT AND HEARING IN CHILDHOOD. By ROBERT B. CARTER and ARTHUR H. CHEATLE. London: The Scientific Press, Limited.

THIS little book is addressed to the laity, and particularly to school managers, with the object of showing how important an influence defective sight and hearing exert upon children. The authors very properly insist that an inquiry into the condition of the eyes and ears should be an essential preliminary to the work of the teacher and to laying plans for the child's future.

A MANUAL OF OBSTETRICS. By A. F. A. KING, A.M., M.D., Professor of Obstetrics and Diseases of Women and Children in the Medical Department of the Columbian University, Washington, D. C. Ninth Edition. Philadelphia and New York: Lea Brothers & Co., 1903.

THE return of an old acquaintance is always a welcome event, and so the reappearance of this tried friend of the student and busy practitioner must be as welcome to the medical profession as the issue of the ninth edition is gratifying to the author. The work is too well known to call for review; it is enough to know that the present edition has been brought abreast of the times, as shown by the introduction of newer and better illustrations and by the rewriting of the portion treating of puerperal infection, and that it remains, as of old, a sure foundation stone to the student of obstetrics—a veritable *multum in parvo*.

A NURSE'S HANDBOOK OF OBSTETRICS. By JOSEPH BROWNE COOKE, M.D., Surgeon to the New York Maternity Hospital. Philadelphia and London: J. B. Lippincott Co., 1903.

THERE is room for an honest difference of opinion as to the amount of technical instruction a trained nurse should receive. Those who believe that the nurse can hardly be aught too much will approve of the scope of this work, but, personally, we feel that it is rather a brief treatise on obstetrics than a nurse's handbook, and that it is neither necessary nor desirable, in a book of this character, to describe at any length such things as the mechanism of labor, the abnormal presentations, the principal obstetric operations or the mode of examining the breast milk to determine approximately its chemical opposition Nevertheless the book is clearly and carefully written, and the profusion of illustration and the minuteness of description must prove helpful to the reader. That the author is alive to the importance of many little things that are too often neglected by trained nurses, and even by physicians who should know better, is shown by his emphatic directions concerning the holding of the fundus uteri after the birth of the child. His remarks upon the establishment of proper habits in the young infant and the need of "saving it from its friends" are also very much to the point.

CONSTITUTIONAL THERAPEUTICS. By A. W. WOODWARD. Philadelphia: Boericke & Tafel, 1903.

THIS volume is dedicated to those physicians who, believing that a scientific therapeutics is attainable, are willing to make a new study of pathology and the physiological action of drugs as conditions essential to that end. The author has evidently made an earnest effort to bring order out of chaos nevertheless to one who has not been brought up in the school of homœopathy, but who is honestly striving after the truth, the result appears to be confusion worse confounded.

PLAIN HINTS FOR BUSY MOTHERS. By MARIANNA WHEELER, Superintendent of the Babies' Hospital, New York. New York: E. B. Treat & Co., 1903

THE author's aim is to help poor and busy mothers to solve the many every-day problems connected with the feeding and general care of babies. Of special merit is the advice about crying babies and the need of supplying only the simplest of toys.

THE LATIN GRAMMAR OF PHARMACY AND MEDICINE. By D. H. ROBINSON, Ph.D., Late Dean of School of Arts, and Professor of Latin Language and Literature, University of Kansas. With an Introduction by L. E. SAYRE, Ph.M., Professor of Pharmacy in, and Dean of, Department of Pharmacy, University of Kansas. Fourth Edition, with Elaborate Vocabularies, thoroughly Revised by HANNAH OLIVER, A.M., Assistant Professor of Latin, School of Pharmacy, University of Kansas. Philadelphia: P. Blakiston's Son & Co., 1903.

THIS is a well-arranged method for the study of Latin in which many of the paradigms and most of the substantives used in the exercises are words in daily use (in their English form) by pharmacists and medical men. At the same time the ingenuity employed in the construction of the sentences is such that there is nothing stilted or forced in the language used. In the latter part of the work many of the reading lessons are composed of selections from Celsus. For the medical or pharmaceutical student who has not studied Latin or who desires to refresh his memory or to supplement a deficient school course in the language, we know of no book which would be of greater help than this. It is so simply arranged, and the quantities are so consistently marked, that the book ought to be as useful for one studying alone as for class work.

The first edition appeared about twelve years ago. In this, the fourth, the changes and additions, shown by experience in the classroom to be advisable, have been made. The vocabularies have been bettered, and a section has been added explaining the English method of pronunciation, as well as the Roman. Most of the additions are such as increase the practical value of an already very good book.

A THESAURUS OF MEDICAL WORDS AND PHRASES. By WILFRED M. BARTON, M.D., Assistant Professor of Therapeutics and Materia Medica, and Lecturer on Pharmacy, Medical Department, Georgetown University; and WALTER A. WELLS, M.D., Demonstrator of Laryngology, Georgetown University; Adjunct Professor of Laryngology, Washington Post-Graduate School; Fellow of the American Rhinological, Laryngological, and Otological Society. Philadelphia, New York, London: W. B. Saunders & Company, 1903.

IF the execution of this unique work had only been as good as its conception there could be naught but praise for the book and for its authors. The aim of the book is well expressed in its title, which is, of course, adapted from that of Roget's: "instead of supplying, as an ordinary dictionary does, the meaning to given words, it reverses the process, and when the meaning or idea is in the mind it endeavors to supply the fitting term or phrase to fit the idea. It aims especially to give the technical equivalents of vernacular or vulgar medical words, and under appropriate headings to present all the technical words associated with a given subject." Had this idea been well carried out, the book would have been invaluable to the medical writer and society debater, but unfortunately there are many deficiencies and inaccuracies in it which render it an unsatisfactory and unsafe guide. Nevertheless, one who knows

his medical language so well that he cannot be misled in its use and who turns to the book only to repair a little break in his memory, may occasionally be helped.

As a justification for this criticism, we will give a few examples of the many errors and omissions which mar the work. Under Mosquito we find Anopheles mentioned as the variety carrying malaria, but nothing is said of the yellow-fever mosquito; culicide (*sic*) is said to be an agent to drive away mosquitos. Abdominal phthisis is called celiophthoe, but of the many alternative expressions not one is mentioned. As a synonym of Body-cavity we are given pleuroperitoneal cavity, but not cœlom or celoma. As a word to express the science of the signs of disease we find only pathognomy, but surely symptomatology, semeiology, and semeiotics should have been included. In a list of "the most important oils" castor oil is not mentioned, nor is mercury found among the "elements with common and technical names." Catalepsy is offered as a word to express "sudden prostration by disease" (p. 146); oligomania, to express "person (*sic*) with insanity on several subjects" (p. 262); veterinary, "surgery of the horse" (p. 468) enenteritis, "inflammation of the peritoneal coat of intestine" (p. 267); kineseonos, "disease marked by impaired motion" (p. 146); analectrotonos and catalectrotonos, respectively "lessened" and "increased" irritability of tissue to stimulation by electricity" (p. 188). These, however, are rather superficial imperfections than intrinsic faults (some of them probably typographical errors), and will doubtless be remedied in future editions. The authors have entered a new field in medical literature, for which they deserve all praise, and it could not in fairness be expected of them to turn out a perfect work at the first trial.

BACTERIOLOGICAL CHART. New York: M. J. Breitenbach Company, 1903.

THIS is a chart arranged to hang on the wall, containing sixty illustrations of the most common microparasites. Most of them are bacteria, but some are amœboid parasites. Not all of the microorganisms represented are established as recognized parasites, as, for example, the assumed microbes of measles, gangrene, whooping-cough, scarlet fever, etc., but they are interesting to study nevertheless. The chart is printed in fifteen colors and has been reproduced from original water-color sketches.

LE SYNDROME URINAIRE DANS LA SCARLATINE ET LA DIPHTHÉRIE DE L'ENFANCE. Par le Dr. RAOUL LABBÉ, Ancien Interne des Hôpitaux de Paris, Ancien Moniteur de Tubage et de Trachéotomie à l'Hôpital Bretonneau. Paris: Jules Rousset, 1903.

THE subject matter of this volume, of such great interest and importance to the physician, considers most comprehensively the urinary syndrome in these two diseases so menacing to the health of childhood. It is really the résumé of investigations carried out in the laboratory of Sevestre at the Bretonneau Hospital. The urine has been studied from all points of view with relation to scarlatina and diphtheria in children. The volume is of great value to those interested in the subject under discussion.

THE GREAT PHYSICIAN. By GABRIEL V. MAX, Historical Painter. Professor at Munich, Hon. Doctor of the University of Jena. Prague: Nicholas Lehmann, 1903.

THIS is a large gravure reproduction of the well-known painting which has been so admired by those who have seen it in exhibitions in this country and Europe. It represents Jesus, the Great Physician, sitting beside the dead daughter of Jairus and in the act of bringing back to her the breath of life. The picture is full of pathos and should carry comfort and hope to all believers in the life-giving power of Christ.

A TEXTBOOK OF CHEMISTRY, for students of Medicine, Pharmacy, and Dentistry By EDWARD CURTIS HILL, M.S., M.D., Medical Analyst and Microscopist; Professor of Chemistry and Metallurgy in the Colorado College of Dental Surgery; Professor of Chemistry and Toxicology in the Denver and Gross College of Medicine University of Denver. With seventy-eight Illustrations, including nine Full-Page Half-Tone and Colored Plates. Philadelphia: F. A. Davis Company, 1903.

As the author states in his preface, this book has been built up from lectures for ten years in medical and dental schools. It is designed for the use of students of medicine, pharmacy, and dentistry. Sixty-nine illustrations and nine plates add much to the attractiveness of the text. The author treats of medical physics, chemic philosophy, inorganic chemistry, the carbon compounds, analysis, incompatibility sanitary chemistry, toxicology, physiologic and pathologic chemistry, clinic chemistry, solubility of common drugs, arithmetic constants, equations of manufacturing chemistry, ores, rocks, and minerals, and popular and alchemic names. The arrangement of the text is convenient, and appeals to the eye. The book must surely prove valuable in the medical library.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and especially prepared original articles on Treatment, Medicine, Surgery, Neurology, Pediatrics, Obstetrics, Gynecology, Orthopedics, Pathology, Dermatology, Otology, Rhinology, Laryngology, Hygiene, and other topics of interest to students and practitioners. By leading members of the medical profession throughout the world. Edited by A. O. T. KELLY, A.M., Philadelphia, U. S. A. Volume II, Thirteenth Series, 1903. Philadelphia: J. B. Lippincott Company, 1903.

STRANGE as it may seem, this issue does not contain one word upon the Finsen light, *x*-ray therapy, or radium. It does, however, deal with many old-fashioned topics, such as summer diarrhœa of children, prophylaxis and cure of influenza, malaria, erysipelas, common colds, valvular affections, cirrhosis in children, sterility, etc. The articles are written for the most part in a conversational or clinical-talk style, which is pleasant to read.

A TEXTBOOK OF VOLUMETRIC ANALYSIS, with Special Reference to the Volumetric Processes of the Pharmacopœia of the United States. Designed for the Use of Pharmacists and Pharmaceutical Students. By HENRY W. SCHIMPF, Ph.G., M.D., Professor of Inorganic Chemistry in the Brooklyn College of Pharmacy; Member of the American Chemical Society; of the American Pharmaceutical Association; of the New York State Pharmaceutical Association; of the Kings County Pharmaceutical Society; of the German Apothecaries' Society of New York City; Honorary Member of the Alumni Association of the Brooklyn College of Pharmacy, etc. With sixty illustrations. Fourth edition, revised and enlarged. New York and London: Chapman & Hall, Limited, 1903.

THIS work has received merited recognition. In this new output advantage has been taken of modern methods of extraction, analysis, and standardization to add descriptions of processes and procedures not possible in former editions. The many methods bearing the name of the inventor which have received due recognition makes quite a list, which indicates in a measure the necessity for this new edition. The student of pharmacy must have such a work, and the aim of this one would seem to be that of a standard.

THE PRINCIPLES OF OBSTETRICS. A Practical Manual for the Student and General Practitioner. By STANLEY PERKINS WARREN, M.D., Portland, Me., Obstetric Surgeon to the Maine General Hospital, Consulting Physician to the Maine Eye and Ear Infirmary, etc. Illustrated by 165 line and half-tone engravings. New York: William Wood & Company, 1903.

WHILE at the first blush it might seem as if the addition of another to the long list of obstetrical treatises extant were a needless contribution to the literature of a subject already rich in excellent manuals, a little consideration of the present volume shows that no such criticism is applicable to it. The author, with unusual judgment, has filled the debatable ground between the bulky system and the sketchy quizz compend, neither of which is adapted to the use of the student or practitioner, and has produced a book exactly suited to their needs. Every phase of the subject is covered, and its most salient features developed in a manner thoroughly in keeping with the most advanced views of modern aseptic obstetrics, and presented in so simple and practical a way as to make the advantages of hospital technique available for the routine work of the average practitioner.

In looking through the book one finds few points susceptible of criticism and many worthy of the highest praise. The measurements of the pelvic brim given on page 8 are decidedly smaller than those usually accepted, and the chapter on embryology would gain greatly by the addition of several diagrams of the development of the fetal membranes, a subject always difficult of comprehension by the student. The sections on percentage, infant feeding, and pelvimetry are especially noteworthy for their completeness and lucidity, and should do much to popularize subjects of the utmost importance for the welfare of child and mother.

The illustrations and presswork are fully worthy of the text, and the volume should prove extremely popular.

THE MEDICAL EPITOME SERIES. MEDICAL JURISPRUDENCE. By EDWIN WELLES DWIGHT, M.D., Instructor in Legal Medicine, Harvard University. Philadelphia and New York: Lea Brothers & Co., 1903

ALTHOUGH a book of only about 250 pages, the practitioner, as well as the student, will find in this much useful information, including general principles, personal identity the causes of violent death, and the medicolegal side of pregnancy, abortion, infanticide, inheritance, insanity, and life insurance. Questions placed at the end of each chapter adapt the book for use by quiz classes.

# Society Reports.

## THE PRACTITIONERS' SOCIETY OF NEW YORK.

*One Hundred and Eighty-first Regular Meeting, Held on Friday, May 1, 1903.*

Dr. JOSEPH D. BRYANT, PRESIDENT, IN THE CHAIR.

**"Some Aspects of the Old and the New: A Plea for Conservatism in Medicine and Surgery."**—Dr. BEVERLEY ROBINSON read this paper (see page 481).

Dr. W. GILMAN THOMPSON, who opened the discussion, commended Dr. Robinson's views in general, and especially his note of warning against the so-called polypharmacy. What has been gained of late years in the abolition of "shot-gun" prescribing has been lost in the bewildering multiplicity of useless new drugs and preparations. The gravest responsibility rested upon teachers of therapeutics and of the practice of medicine to see that the student and young practitioner shall take the right view of medicines, and not be beguiled or bewildered by an enormous number of new remedies, the uselessness of which he was otherwise likely to learn only through the experience of his unfortunate patients. The editors of pharmacopœias and dispensatories might well have the courage to eliminate nine-tenths of the drugs and preparations which they persistently describe.

Dr. G. L. PEABODY said he had been very much interested in Dr. Robinson's paper, and thought that while it was full of suggestions, it was rather difficult to discuss. He agreed with the writer of the paper, but would go one step further in the use of hydrotherapy. As time went on, the medical profession was making more use of this therapeutic agent. He thought that hydrotherapy, used in pneumonia, delirium, and certain high fevers, invariably gave better results than drugs, especially the coal-tar derivatives, and was not so depressing to the patient. "Polypharmacy" was due, in a great part, either to laziness or ignorance on the part of the physician.

Dr. J. W. BRANNAN said he thought that the society was greatly indebted to Dr. Robinson for presenting this paper. In regard to unnecessary operation, he could scarcely recall a case in which the operation was uncalled for in his practice, but he had heard of cases in which such operations had been performed. Dr. Brannan thought that cirrhosis of the liver opened up a new field of operation in a certain number of cases in which medicine could do nothing. He spoke of a patient with cirrhosis and ascites who got well after an operation. He agreed with Dr. Thompson in regard to the wisdom of discarding a great many drugs. He recalled a case in which trional was administered for sleeplessness, and the patient developed alarming symptoms; since then he had been more careful in using this drug.

Dr. F. P. KINNICUTT said he was quite in accord with the conservatism of Dr. Robinson's paper. Dr. Robinson had referred to the self-limitation of many diseases. It was important that not only the self-limitation should be borne in mind, but also the natural remissions and exacerbations that occur in many chronic affections: Graves's disease and pernicious anæmia were striking examples of this fact. In Graves's disease the natural remissions and exacerbations in many of the symptoms were such that it was exceedingly difficult to judge of the effect of any method of treatment. Personally, Dr. Kinnicutt had seen little effect from drugs in this disease, but a great deal certainly could be accomplished by the regulation of the patient's life, environment, etc. Again, in pernicious anæmia, natural remissions of varying and indefinite periods occurred in which the blood condition improves to an extraordinary degree, occasionally reaching its normal quality, and this with or without the administration of drugs. Dr. Kinnicutt's experience was in accord with Dr. Peabody's regarding the value of hydrotherapy. In the disturbances of the nervous system in many acute infections, he had learned to depend much more on hydrotherapy than upon drugs. In the acute delirium not infrequently present in the course of pneumonia in adults, a cold pack often succeeded in relieving the symptom when drugs were quite useless. Again, a full bath at 90°, as a rule, would quiet the violent disturbances of the nervous system so often present in young children at the onset of this disease.

Dr. E. G. JANEWAY said that all that had been expressed by Dr. Robinson was in the main very judicious, and that the discussion had been so satisfactory that there was little left to add. He would consider the paper, however, from two points: first, that at times we are thought to be too conservative in our surgery. He mentioned instances that had come under his observation with carcinoma of the stomach where it would have been wiser to have operated at an earlier date, and as regards operation in some of the cases of this character in which the condition was so serious that a radical procedure was out of the question, that he thought the patient had to decide whether he would be willing to have palliative surgery, with the hope that he could obtain a more satisfactory existence while life lasted. He mentioned that of the three last cases which he had seen of operation for carcinoma toward the pyloric extremity, one patient died as a result of the operation; one made a very positive gain of fourteen pounds in six weeks, and felt at the end of that time perfectly well, though the tumor still persisted and could be made out; in the third the operation was successful, but the gain had not been so considerable as in the second case. If in these cases operation could have been performed at an earlier period, there might have been still better results. In carcinoma of the intestine, the same thing was true; the diagnosis was so often arrived at so late a period that only palliative measures were available. It seemed to him that at times it would be wise, choosing judiciously, to do an exploratory incision to determine certain of these cases. As regards the medical side, Dr. Janeway agreed with Dr. W. Gilman Thompson that we have too many drugs; in iron, for example, a few preparations would be preferable to the many that are now in the books, and the same was true of other drugs. He said also that at times the coal-tar products had a distinctly serviceable field in fever, particularly in those cases in which there was idiosyncrasy against the use of the tub. He mentioned one case to show how little might be of service; it was that of an adult in whom one grain produced all the results desired, five grains producing a greater influence than was wished.

## AMERICAN DERMATOLOGICAL ASSOCIATION.

*Twenty-seventh Annual Meeting," Held at Washington, D. C., May 12, 13, and 14, 1903.*

**Special Report to the Medical Record.**

(Continued from page 479.)

*Wednesday, May 13—Second Day.*

**Some Observations on the Use of Röntgen Rays in Dermatology.**—By Dr. HENRY W. STELWAGON of Philadelphia. In this paper the author limited himself essentially to his own observations. He stated that in the *x*-rays we had a potent remedy in some cutaneous diseases, chiefly in some of the epitheliomata. It was also productive of benefit and even cure in some cases of lupus, scrofuloderma, and other forms of cutaneous tuberculosis, and it would probably prove a permanent curative influence in some cases of lupus erythematosus. In other skin diseases, more especially acne of stubborn type and in acne rosacea, its effects were occasionally brilliant. In certain limited keratoses, especially of the palms and soles, it might be resorted to with a good chance of its being beneficial and occasionally curative. The same might be said also of the local forms of hyperidrosis. In eczema, psoriasis, and other like comparatively inoffensive dermatoses he would

reserve it for those cases which proved intractable to other plans of treatment. While recognizing the great value of this therapeutic agent in dermatology, and that future observations might give it a still stronger hold, he hesitated, as yet, from his own relatively limited experience, to subscribe without reservation to its possession of the almost marvelous powers accredited to it by other writers in so large a number of dermatoses.

**The Rationale of, and the Indications for, the Therapeutic Use of Röntgen Rays.**—By Dr. WILLIAM A. PUSEY of Chicago. The author stated that the microscopical changes occurring in tissues affected by *x*-rays have been studied by various observers, and their findings showed a striking uniformity. The first changes occurred in the epidermis. There was marked hyperplasia of the prickle-cell layer, with increase in the number of cells, and increased formation of pigment and of keratohyalin, followed after further exposure by breaking up of nuclei or division of the nuclei; subsequently, there was degeneration of the cells, and if the process proceeded further, complete disintegration. The changes in the corium were of a similarly striking character. The changes produced in diseased tissues were similar to those seen in normal tissues. The process was one primarily affecting the tissue cells; there was evidence first of stimulation of cellular activity, and later, if the effect was intense, there followed derangement or disintegration of the affected cells. The changes occurred first and most strikingly in the epithelial structures and next in the blood vessels, but it was likely that they developed also, though to a much less degree, in the cells of all the tissues of the affected areas. From a consideration of the effect of *x*-rays upon tissues and upon bacteria in living tissues it was not difficult to arrive at a fairly accurate estimate of the indications for the therapeutic use of this agent. The actions of the *x*-rays which offered opportunities for therapeutic application were as follows: (1) The action in causing atrophy of the appendages of the skin. (2) The destructive action upon organisms in living tissues. (3) The effect upon the metabolism of tissues. (4) The power of destroying certain pathological tissues. (5) The anodyne action, to which attention had been called by the effect upon pain in malignant growths, in neuralgias, and in diseases of the skin accompanied by itching.

Dr. L. A. DUHRING of Philadelphia said he was firmly impressed with the value of the Röntgen rays as a therapeutic agent in numerous diseases. He favored the use of the low vacuum tube.

Dr. JAMES C. WHITE called attention to the possible injurious effects of the rays, even when the applications were made by men of great experience in the handling of the apparatus. The ultimate use of the rays should be confined to cases in which the knife or cautery was not considered advisable.

Dr. L. DUNCAN BULKLEY of New York emphasized the importance of measuring the dose of the remedy. He favored short exposures at close range, and not too frequently repeated.

Dr. F. H. WILLIAMS of Boston said that while the *x*-rays offered a remedy of much value in the treatment of skin diseases, it should be used with the greatest care. Some cases of even superficial new growths did not yield readily to the treatment, and in some instances they were actually aggravated by it. Such cases, however, were uncommon. Another disadvantage was the long duration of the treatment.

Dr. WILLIAM A. HARDAWAY of St. Louis said that while all were agreed as to the utility of the *x*-ray in malignant new growths of the skin, particularly in that type of growth approaching the rodent ulcer, there was some legitimate reason to doubt its value in acne and various other forms of skin disease. He also spoke of the relapses that occasionally followed the treatment.

Dr. E. B. BRONSON said the value of the *x*-rays was, in more ways than one, the burning question in therapeutics. In the application of the remedy there was still lacking a certain degree of precision. The essential feature was the amount of irradiation, and this depended, he thought, upon the condition of the tube. The actuating element he regarded of less importance.

Dr. HARTZELL said that until physicists told us what the *x*-rays were, and furnished us with apparatus to gauge the strength of the rays, we would be limited to the effects they produced. The time of the exposure must be determined by the effect produced. The same rule applied to other therapeutic agents. The proper dose in one case would be insufficient in another, and too much in a third. He favored short exposures daily until a reaction occurred; then the intervals could be lengthened.

Dr. FRANK HUGH MONTGOMERY of Chicago said that in the treatment of superficial epithelioma about the forehead, nose, and cheeks with the *x*-rays, he had not seen one failure in at least over one hundred cases. In psoriasis the results were brilliant almost invariably, but the lesions recurred as fast as after other methods of treatment. In lichen planus the results were excellent. In acne he looked upon it as the ideal local treatment, but there were quite a number of cases in which, after the face had cleared, there was a return of the disease from outside.

Dr. F. H. SHEPHERD said that *x*-ray burns were usually produced in the course of skiagraphic work and not in the treatment of skin diseases. He did not think the use of the *x*-rays should be advised in the treatment of epithelioma of the lower lip, on account of the usual involvement of the glands in the submaxillary region.

Dr. MARTIN F. ENGMAN of St. Louis cited a case of epithelioma of the tongue successfully treated by the *x*-rays.

Dr. A. P. BIDDLE of Detroit mentioned a case in which the tube exploded, badly cutting the patient's cheek.

Dr. JOHN T. BOWEN of Boston gave a brief review of the result of the Röntgen ray treatment in dermatology in the Massachusetts General Hospital during the past year. In all, 143 purely cutaneous diseases were treated by this method. This number was made up as follows: There were 55 cases of epithelioma, of which 27 were healed, nine were benefited but failed to continue treatment, and 19 were still under treatment. There were 4 cases of carcinoma; these were not benefited. Seventeen cases of keratosis senilis, 11 of which were cured, 4 were benefited but failed to continue treatment, and 2 were still under treatment. There were 22 cases of tuberculosis, including lupus, verrucosa and scrofuloderma; 15 of these were healed, 4 were benefited but failed to continue treatment, and 3 were still under treatment. There was one case of multiple round-cell sarcoma of the skin which was not benefited. There were 12 cases of folliculitis, 8 of which were healed, 2 were benefited but failed to continue treatment, and 2 were still under treatment. There were 7 cases of eczema, 5 of which were healed and 2 were still under treatment. There were 8 cases of psoriasis; 6 healed; 2 still under treatment. There were 4 cases of varicose ulcer; 2 healed; one benefited but failed to continue treatment; one still under treatment. There was one case of cellulitis of the leg, which failed to show any improvement. Two cases of varicose dermatitis; one healed; one benefited but failed to continue treatment Two cases of acne; both healed. Two cases of hypertrichosis; both healed. Two cases of alopecia areata; not benefited. One case of erythema induratum; healed. One case of scleroderma; not improved. One case of hyperidrosis; not improved.

**Professional Discretion: The Medical Secret.**—By Dr. P. A. MORROW of New York. In this paper the author discussed the complicated problems that often confront the physician in dealing with patients suffering from venereal diseases. On the one hand, he was bound by the obligations formulated in the precepts of the Hippo-

cratic oath; on the other, by his duty to society at large. In the ordinary treatment of venereal disease he found it easy enough to adjust his line of conduct in strict accordance with his code of professional duty, as in such cases the individual interests of the patient alone were involved, but when a venereal patient consulted a physician in regard to marriage, the situation was changed: then the interests of others might be jeopardized. His protective duty extended to the wife and future children, and through them to society at large. There was no situation in the entire range of a professional man's experience so painful as to recognize himself powerless to prevent the morally culpable union of a syphilitic man and an innocent woman. What had been termed the "eternal problem" of the professional secret had long engaged the thoughtful attention of medical men. Like all problems connected with the prophylaxis of venereal disease, it was exceedingly complex and baffling. It might be said that no solution of these problems had ever been proposed, no plan of action for the regulation or control of these diseases had ever been formulated which did not come in conflict with individual liberty, legal rights, or moral principles. In the larger proportion of cases, venereal diseases were introduced into marriage from extra-conjugal infections, contracted *post nuptias*. Here it was evident that the preventive duty of the physician could not be exercised. Other phases of the subject discussed by Dr. Morrow in his paper were the relation of the physician to the syphilitic husband or wife, to the syphilitic nurse, syphilis in domestic servants, and lastly, industrial infections.

Dr. GILCRIST said he thought syphilis should be regarded from the same standpoint as smallpox. It should be looked upon as a highly contagious disease.

Dr. STELWAGON called attention to the fact that many hospitals refused to accept venereal patients on the ground that it would encourage vice. Physicians themselves, he thought, were partly to blame for the increase in venereal diseases, as they were too apt to belittle this class of affections.

Dr. H. G. KLOTZ of New York advised the wide dissemination of a knowledge of the dangers attending the contraction of venereal diseases. The subject should be handled without gloves. Syphilis was not a venereal disease, but a disease of the public.

**Note on a Method of Early Diagnosis in a Case of Leprosy.**—By Dr. FRANCIS J. SHEPHERD of Montreal. The patient, a Chinaman, was admitted to the Montreal General Hospital with a skin affection of an erythematous type. Leprosy was suspected. and the city authorities were anxious for a positive diagnosis in order that the patient, if suffering from leprosy, might be sent home. The ulnar nerves were enlarged. A section was removed from one of them, and on examination it was found to contain numbers of the bacilli of leprosy. Thus the diagnosis was positively established.

Dr. FRANK H. MONTGOMERY of Chicago called attention to the early involvement of the posterior auricular nerve in leprosy. According to one authority, it was involved in 90 per cent. of all cases of anæsthetic leprosy, and much earlier than the ulnar nerve.

Dr. MORROW said that in a very large proportion of cases of leprosy the identification of the lepra bacillus was easily made in the nasal secretions.

**Dermatitis Venenata—A Supplemental List.**—By Dr. JAMES C. WHITE of Boston. In this paper the author placed on record for convenient reference a list of the agents which had been observed to produce inflammation of the skin by contact since the publication of his work on "Dermatitis Venenata" in 1887. Some of these had already been described by him from time to time. The list included chlorhydrat-paraphenyl-diamin (found in certain hair dyes); aureole, also used as a hair dye; orthoform; salol; resorcin; aristol; ichthyol; dermatol; europhen; pyoctanin; creolin; iodvasogen; kerosene; electricity; aurantia, an orange colored dye used to stain leather; cocus wood; guiacum; humulus; heracleum; angelica; hyacinth; Ginkgo tree; cotoneaster; humea.

Dr. MORROW called attention to the importance of a very thorough investigation in every case of dermatitis venenata. Many innocent plants had obtained a bad reputation for toxic effects simply from misinterpretation.

Mr. V. K. CHESNUT of the U. S. Department of Agriculture said the most common causes of skin poisoning from plants were the poison-ivy and the sumac, both of which were very widely distributed in this country. He stated that persons who handled radishes in abundance were apt to be poisoned.

Dr. STELWAGON said that the drug metol, used by photographers in the development of negatives, often produced a varying degree of dermatitis of the hands and sometimes of the face.

Dr. GILCRIST mentioned a case in which an eczematous eruption was produced by a weak solution of boracic acid, used as a rectal injection.

Dr. KLOTZ said he had observed the same thing in cases in which the drug was used for irrigating the bladder in cystitis.

Dr. James C. White, in closing, said that while it was a popular belief that ivy poisoning might recur spontaneously a year after the original attack, he did not regard that theory as at all plausible; there were no grounds for it. On the other hand, the skin of a person who had once been poisoned by ivy was no doubt more susceptible, and with the onset of warm weather eczematous lesions or other forms of dermatitis might occur. It was well known that the poison of the ivy vine was quite evanescent.

**A New Drug Eruption of the Iodoform Type.**—Dr. S. POLLITZER of New York read this paper. He reported a number of cases of dermatitis, of a vesicular and crusted type, resulting from the external use of mesotan, which was described chemically as a methyl-oxymethyl-ester of salicylic acid. Mesotan was a comparatively new remedy for rheumatism, and was applied externally over the affected parts, after diluting it with an equal volume of olive oil. The local application of the remedy was promptly followed by an agreeable sensation of warmth and tingling, the skin became reddened, and within half an hour after its application salicylic acid could be detected in the urine.

**Report of a Case of Dermatitis Gangrænosa Infantum.**—By Drs. J. NEVINS HYDE and E. R. LECOUNT of Chicago. The patient, an infant seventeen months old, had always been in good health, with the exception of a single attack of bowel disorder, from which it had promptly recovered. It had walked at the twelfth month and had accomplished the normal eruption of teeth. There was no history of varicella, variola, or vaccination. The family history was good, and there was no record of unhygienic surroundings in the home. The child was admitted to the hospital on February 15, 1903. Ten days before, the mother had first noticed some reddish blotches on the abdominal surface of the child. Two days later, beginning with the left hand, the fingers became yellowish-red in color and much swollen. Gradually, the involved digits assumed a darker hue. A physician was summoned on the third day, who incised the tumefaction between the fingers, with the result of liberating a "watery fluid." On the fifth day of the disease, eruptive lesions appeared on the back, the feet became swollen and much discolored. At the time of admission, the child's temperature was 104° F.; there was considerable stupor and the child moaned occasionally. The abdominal surface was symmetrically and rather thickly overspread with superficial, globular, discrete pustules, as large as split peas, well defined and distended, and having a grayish-white color. They were neither umbilicated nor superimposed upon papules of similar size. On the extremities they were less numerous and conspicuous. The back was equally involved with

the abdominal surface, but the lesions were obviously more abundant in the regions of pressure. On the eleventh day a marked change occurred in the eruptive phenomena, superficial papulopustules cropping out among the pustulobullous lesions, and these were decidedly more numerous and more deeply encroaching gangrenous areas where the lesions were large and threatening. The parts about the radial border of the left hand were in a gangrenous state. The left foot was swollen, cold and blackened; the right foot was similarly involved, though less extensively. Several of the digits of both the hands and feet were attached to the limb merely by tags of gangrenous tissue, and eventually one of them became practically separated from the limb by the morbid process. Death occurred on the fifteenth day of the disease.

**Report of a Case of Symmetrical Gangrene.**—Dr. E. B. BRONSON of New York reported a case of symmetrical gangrene affecting the lower extremities. The patient was a girl who had always apparently enjoyed good health. She was thirteen years old when the affection was first noticed. The family history was fairly good, although it showed some gouty and neurotic tendencies. The patient had had no severe illness, and though of a nervous temperament, she possessed good self-control and normal mentality, and had never given the slightest indications of hysteria. The disease began some eight years ago, and from beginning to end had occupied the same regions. The lesions were exactly symmetrical. There were areas over the shins, at the juncture of the middle and lower third of the legs and on each side of both ankles behind the malleoli. The first attack came on in summer and for several years the succeeding attacks occurred in that season. About five years ago they began to occur in the winter also. Their most important feature was pain, which was both burning and lancinating in character, and at times intense. This was accompanied with a dusky redness, heat and swelling, and occasionally excoriations; the latter the patient thought were usually the result of the severe treatment to which she was subjected, namely, caustics, and at times curetting. There was never any ischæmia nor coldness of the affected parts. The attacks lasted usually about six weeks, and there were seldom more than two or three attacks in the course of a year. At one time, some two years ago, there was an intermission of eighteen months between the attacks. Commencing last May or June, there was a continuous attack lasting until the middle of October; it was the severest of all, and attended by the development of deep gangrene—usually on the shins. After the gangrene had reached its fullest extent, the pain rather suddenly ceased, but the dry, black sloughs showed very little tendency to separate, and after waiting a month or more they were removed by the knife, it being necessary to cut almost to the bone before reaching healthy, living tissue. Since then (six months ago) there had been no recurrence of the disease.

*Thursday, May 14—Third Day.*

**A Case of Multiple Angioma.**—Dr. ABNER POST of Boston reported this case. The patient was an undersized but apparently healthy girl of sixteen who bore upon her right arm a series of curious outgrowths or tumors which practically occupied the whole of the palm and extended in scattered nodules to the sternum. The first growth appeared on the arm when the patient was one year old. The arm gradually became swollen, of a bluish color and an irregular, lumpy outline. Shortly afterward a puffiness of the hand was noticed, which also underwent the same change. During the past six or seven years similar spots had developed on the chest. Six years ago a number of the superficial elevations were cut away, but they recurred in practically the same locations. A microscopical examination of the tumors proved them to be hæmangiomata.

**The Present Status of Phototherapy.**—By Dr. FRANK HUGH MONTGOMERY of Chicago. The paper was based on the author's recent observations in the Copenhagen and other light institutes, on published reports, and on the personal experience of Dr. James Nevins Hyde and his own. He stated that in lupus vulgaris no other treatment was so uniformly successful or gave such good results from a cosmetic standpoint. The *x*-rays had given equally good results in some cases, but were more dangerous, and the resulting scars were not always so good. Phototherapy was also of great value in the treatment of lupus erythematosus. It had given good results also in some cases of rosacea, vascular nævi, alopecia areata, indolent ulcers, acne and superficial epithelioma. In the two last named diseases, the *x*-rays were, however, equally efficacious, more convenient and less expensive. In Finsen's Institute (Copenhagen), as the result of improvements in the apparatus, the time (and, therefore, the expense) of the treatment had been reduced to one-fourth that required in cases treated prior to 1901. A new and inexpensive lamp for the treatment of a single patient had been devised by Professor Finsen and Dr. Reyn. It was built on the same principles as the larger apparatus, and was equally effective. Of the many other small lamps on the market, some were of value in the treatment of superficial lesions, but, as shown by clinical and laboratory tests, none had the penetrating power of the concentrated Finsen light, and all were therefore ineffective in deeper-seated disease. The most refrangible ultraviolet rays, which were highly bactericidal for surface cultures, penetrated the epidermis less than one millimeter. The effective light was found in the visible blue and violet, with possibly a few of the immediately adjacent ultraviolet rays. Finsen believed that the reported failures of the red-light treatment of smallpox were due to imperfect technique. He hung in the room with the patient a number of sensitized photographer's plates: if, at the end of the treatment, these plates showed the influence of white light, the technique had been defective.

Dr. GEORGE THOMAS JACKSON of New York showed one of the small lamps devised by Dr. Piffard, which was very rich in ultraviolet rays. The London lamp had been used at the Presbyterian Hospital during the past year, with varying success. In one case of epithelioma of perhaps six months' standing, the lesion, which was a superficial one, disappeared after three exposures of the light. Regarding the length of the exposure, Dr. Jackson said he had no fast rule. Sometimes an exposure of five minutes gave rise to an intense dermatitis, while in another case there might be no reaction after an exposure of twenty-five minutes.

Dr. WILLIAM A. PUSEY of Chicago said he had been interested in comparing the effects of phototherapy and radiotherapy, and it seemed to him that there were one or two conditions in which the former was preferable. There was a field of usefulness for phototherapy in the treatment of flat nævi and in conditions in which it was desirable to produce an inflammatory reaction and be on the safe side. It was safer than radiotherapy.

Dr. E. B. BRONSON said the effective agent in phototherapy was not the ultraviolet rays alone or even chiefly. Finsen had demonstrated very effectively, by experiments on rabbits, that there was a wide disparity between the penetrability of the different lamps. The penetrability depended not on the ultraviolet rays alone, but on the visible rays as well.

Dr. MONTGOMERY, in closing, said there was no question that light rays were highly bactericidal on the surface; the vast majority of bacteria were destroyed very rapidly by the ultraviolet rays.

**Some Precancerous Affections of the Skin, More Particularly Precancerous Keratoses.**—Dr. M. B. HARTZELL of Philadelphia read this paper. He stated that a small number of diseases of the skin, after existing for a longer

or shorter period as benign affections, exhibiting neither the clinical nor the histological features of malignancy, might terminate in epithelioma. This termination, although far from being the rule, occurred in a sufficient number of cases to exclude the probability of mere coincidence, and to warrant the application of the term precancerous to such affections. These diseases did not belong to a single pathological group, but included inflammations, neoplasms, hypertrophies and such alterations of the skin as might result from previous disease or injury. In this list of precancerous affections Dr. Hartzell included the following: Paraffin dermatitis, a peculiar inflammation of the skin occurring in workers in tar and paraffin; the dermatitis of the scrotum met with in chimneysweeps, due to the irritation of soot; lupus vulgaris, in a small proportion of cases; other forms of cutaneous tuberculosis, such as tuberculosis cutis verrucosa; rarely after lupus erythematosus; new growths of the skin, congenital or acquired; pigmented nævi; chronic leg ulcers; cicatrices arising from any cause, but more particularly those resulting from burns; various forms of circumscribed keratoses, such as cutaneous horns and callosities; arsenical keratoses; the so-called senile seborrhœa, a better name for which was the senile keratoma of Besnier. The latter Dr. Hartzell regarded as the most frequent and perhaps the most important form of precancerous keratosis.

Dr. JAMES C. WHITE of Boston mentioned a case of epithelioma of the hand following a prolonged *x*-ray dermatitis.

Dr. PUSEY said he had recently had the opportunity of studying a remarkable case of chronic *x*-ray dermatitis in a man who manufactured apparatus for producing the rays. He was burned from the middle of the trunk upward, the lesions resembling those of xeroderma pigmentosa. Subsequently he developed an epithelioma, for which his hand had to be amputated.

Dr. STELWAGON said he had seen a number of examples of chronic *x*-ray poisoning in which there were decided keratoses that pointed suspiciously toward the development of epithelioma.

Dr. MARTIN F. ENGMAN of St. Louis said he thought that sunlight might possibly have something to do with the development of senile keratoses. The lesions occurred most frequently on exposed parts.

Dr. L. A. DUHRING reported a case of typical lupus erythematosus followed by the development of a carcinoma. He had never seen a similar case.

Dr. S. POLLITZER of New York thought that epithelioma following lupus, whether of the vulgaris or erythematosus type, might depend upon the mechanical methods of treatment employed. Otherwise it was difficult to see why an inflammatory process like lupus should result in epithelioma more frequently than any other inflammatory disease.

**Paludides with the Histopathology of a Case of Malarial Purpura.**—By Dr. MARTIN F. ENGMAN of St. Louis. In using the word paludide, the author followed the suggestion of Verneuil and Merklen and also Brocq to express the probable origin of certain familiar eruptions associated with malarial infection. In the cases he reported, twenty-four in all, the malarial plasmodium was demonstrated in the blood. The list included herpes simplex, herpes zoster, pompholyx, urticaria, angioneurotic œdema, trophic changes in the skin (non-inflammatory pityriasis), erythema multiforme, purpura, and gangrene. He did not attempt to express an opinion as to why so many different types of eruption should emanate from the same source, nor did he wish to be understood as claiming that these eruptions were peculiarly malarial in origin; therefore the term paludide was not used in the sense that one employed the word tuberculide or syphilide. The object of the paper was to point out the necessity of blood examinations in eruptions with any semblance of periodicity of their symptoms. Many of the paludal dermatoses were not accompanied by any constitutional symptoms, pyrexia, chills, etc., the dermal symptoms being the only manifestations of the infection. In the histologic examination of a paludal purpura the lymph channels were widely dilated, the superficial vessels were empty and the deeper ones engorged. There were marked symptoms of œdema, and slight diapedesis of red cells from the deeper vessels. No thrombi were found.

The President, Dr. BOWEN, said he did not think the term "paludides" was an especially fitting one. While malaria was the cause of the eruptions in the cases reported by Dr. Engman, similar eruptions were also produced by other causes.

The following officers were elected for the ensuing year: *President*, Dr. Joseph Zeisler of Chicago; *Vice-President*, Dr. M. B. Hartzell of Philadelphia; *Secretary and Treasurer*, Dr. Charles J. White of Boston. Niagara Falls was selected as the next place of meeting, which will be held early in June, 1904.

## Books Received.

*While the* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

HIGH-FREQUENCY CURRENTS IN THE TREATMENT OF SOME DISEASES. By CHISHOLM WILLIAMS, F.R.C.S., 8vo, 222 pages. Illustrated. Rebman Co., New York City. Price, $2.75 net.

CANCER AND PRECANCEROUS CHANGES, THEIR ORIGIN AND TREATMENT. By G. H. FINK, M.R.C.S. 8vo, 105 pages. H. K. Lewis, London, England.

CONSUMPTION A CURABLE AND PREVENTABLE DISEASE. By LAWRENCE F. FLICK, M.D. 12mo, 295 pages. David MacKay, Philadelphia, Pa. Price, $1.00.

A COMPEND OF HUMAN ANATOMY. By SAMUEL O. L. POTTER, M.D. Seventh edition, 12mo, 372 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia. Price, 80 cents net.

A COMPEND OF DISEASES OF THE SKIN. By JAY F. SCHAMBERG, M.D. Third Edition, 12mo, 291 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia. Price, 80 cents.

A HANDBOOK OF THE DISEASES OF THE EYE AND THEIR TREATMENT. By HENRY R. SWANZY, M.B. Eighth edition, 8vo, 580 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia, Pa. Price, $2.50 net.

A TEXTBOOK OF THE DISEASES OF WOMEN. By THOMAS A. ASHBY, M.D. 8vo, 661 pages. Illustrated. Williams & Wilkins Company, Baltimore.

**Should the Deaf Be Debarred from Accident Insurance?**—J. A. Spalding, who suffers from deafness and who has been turned down by one of the accident insurance companies, complains of this action, and declares that a deaf person is as good a risk against pedestrian accidents, at least, as one who can hear well, owing to the greater care which the deaf person takes of himself, because of his very defect and owing to his better perception of sounds in the noise of the streets than in the case of those who can hear He bases these conclusions on personal experience supplemented by considerable thought and study. —*Archives of Otology*.

**What Will Tuberculin Do?**—In a paper read before the International Congress on Tuberculosis held in Italy, Gustav Schmidt thus described the effects we may look for from the use of tuberculin: (1) In hereditary or acquired predisposition to the disease tuberculin will establish immunity by increasing resistance to the tubercle bacillus. (2) Incipient cases can be permanently cured and relapses do not follow. (3) In advanced cases without mixed infection the disease may be cured, stayed, or improved. (4) Cases in the last stage are temporarily improved and the distressing symptoms are relieved

# Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 19, 1903:

| | Cases. | Deaths. |
|---|---|---|
| Measles | 62 | 3 |
| Diphtheria and croup | 182 | 23 |
| Scarlet fever | 88 | 6 |
| Smallpox | 1 | ... |
| Varicella | 12 | ... |
| Tuberculosis | 301 | 122 |
| Typhoid fever | 102 | 16 |
| Cerebrospinal meningitis | ... | 4 |

**Attack on United States Census Figures.**—At the Fourth International Congress of Actuaries, recently held in New York, Mr. Frederick Hoffman of Newark seized the occasion to criticise severely the manner in which official statistics of the United States, and especially of the Census Bureau, are collected. "When we are told," he said, "by a secretary of war that the mortality of the army in Cuba was not greater than that of the city of Washington we do not need large actuarial knowledge to smile at the statement, and to dismiss as without statistical value—a misleading item disseminated to an ignorant public for political purposes." Mr. Hoffman asserted that although the United States Census Bureau was not "in such atrocious shape" as it had been before it became a permanent department, yet "it was very far from being such as to give its statistics value as contributions to science." Mr. Hoffman also commented upon the effect of improper drainage on the death rate, and said that until the drainage conditions in the Southern States are improved, the average of longevity there cannot be so great nor the lives so well developed as in the cities of the North.

**London Fogs.**—The Bulletin of the American Geographical Society says, regarding London fogs, that Captain Alfred Carpenter, R. N., who has been conducting the official inquiry into the occurrence and distribution of fog in London, has presented a report to the Meteorological Council of the Royal Society on the results obtained for the year 1901-'02. Among the most important conclusions thus far reached are the following: The commencement of a fog is a general process, depending upon general atmospheric conditions. There is no evidence that fogs formed outside invade or drift into London. London fogs are produced in London. During dense fogs there is a tendency to an indraught of air from all sides to the central parts of the city. No severe fog has occurred with a temperature above 40°. On March 7, during a fog, the temperature in the streets was nearly 10° below that on the roof of the meteorological office, at the elevated stations, and over the surrounding country on the south and west. It is proposed to carry on the investigation, and especially to study the vertical decrease of temperature before and during fogs.

**The Sneeze and Its Diagnostic Value.**—It is reported that Mr. Jonathan Hutchinson has said that "when a man sneezes heartily he may know himself to be in the best of health," and that "no person in poor health was ever known to sneeze." The *Scientific American*, referring to this reported statement, falls foul of the English surgeon for making so dogmatic an assertion when the contrary is so easily proven. The journal in question then goes on to relate many old superstitions with regard to the ill luck attending sneezing, some of which, while proving nothing, are interesting. It appears that many savage and semi-civilized races of the Orient have some curious customs regarding the sneeze. When the Sultan of Monomtopa sneezes, for instance, the fact is made known from the palace by a certain signal. Instantly every subject within hearing of the signal sets up a shout; the cry is taken up by others, and so extends until it rolls through the confines of his empire. When the Sultan of Senaar sneezes, on the contrary, every woman in his harem or within hearing, turns her back on him and makes a sign of contempt by smiting her hips with her hands—disgusted that so mighty a personage should have to sneeze like an ordinary mortal.

**Medical Students at Swiss Universities.**—The Swiss correspondent of *The Lancet* writes that during the winter term 1902-03, 1,696 duly matriculated medical students attended the five Swiss universities, being an increase of 203 as compared with 1,493 in 1901-02. This increase was especially marked with regard to the universities of Bern, Lausanne, and Zürich, whereas the number at Basle remained the same and at Geneva it had decreased. This increase of medical students is principally due to the circumstance that 840 female students are now studying medicine at Swiss universities, whereas there were only 665 in 1901-02. The number of female students of Swiss nationality was quite small, the overwhelming majority being Russians. This is accounted for by the fact that on the one hand it is difficult for women to study medicine and become qualified in Russia, whereas on the other hand the Swiss degree of M.D. is recognized in Russia. It is understood, however, that the Russian Government proposes to diminish the obstacles which female students at present have to encounter in that country. It has been suggested that one medical school in German-speaking Switzerland and one in French-speaking Switzerland (obviously Bern for the former and Lausanne for the latter, where the female students number respectively 66 per cent. and 57 per cent. of the total number of students) should be transformed into faculties receiving only the gentler sex.

**The Application of the Cinematograph Principle to the Study of Serial Sections.**—Mr. Robert E. Kelly of University College, Liverpool, has been making some interesting experiments in the application of the cinematograph principle to the study of serial sections, the results of which he has published in the *British Medical Journal* of August 8. He was struck by the resemblance between the pictures on a cinematograph film and a series of sections in a paraffin ribbon, and determined to try the effect of viewing these sections on the cinematographic principle. Mr. Kelly accordingly mounted, on a clear celluloid film twenty-five feet long, 700 serial sections from the head and neck of a chicken embryo six days old, and he says that the result is extremely interesting and curious, for the impression produced is that of traveling through the embryo. The eye, for instance, appears first as a dot; this changes to a ring, the ring enlarges, then near the periphery another dot appears. This is the lens; it gets larger, takes on its proper shape, then diminishes and fades away; the ring gets smaller, and the eye finally disappears as a dot. The method of mounting is thus described: The tissue is fixed, stained and imbedded in paraffin in the usual way, and a paraffin ribbon formed in a microtome. As the celluloid film is stainable, and as the subsequent proceedings are rendered easier, the tissue has been stained in bulk. The "ribbon" is then floated directly on to warm water and stuck on to the celluloid film by means of an albuminate fixative. At first the larger films were tried, in which the pictures are three-quarters of an inch apart, but these have been discarded in favor of the smaller, three-eighths of an inch. Now it follows that if the paraffin block from which the sections are cut is exactly three-eighths of an inch wide and has its sides perfectly parallel, then the resulting ribbon will be straight and have its sections exactly three-eighths of an inch apart. Practically they never quite float out to this size unless the water is too hot, consequently the block is cut a shade larger than three-eighths of an inch. Having, therefore, properly indexed the sections, the whole film is dried on a barrel, and then the paraffin is dissolved in xylol and the sections fixed on the film by means of a varnish. Covering

is out of the question, and Canada balsam cracks when it is rolled. In future better results will be obtained with a gelatin cover. Oil of cloves cannot be used, as it destroys the celluloid film. When thoroughly dry, the film is rolled up and placed in the cinematographic apparatus. Then the sections are projected on the screen by means of the camera, or the working portion of the cinematographic camera is placed on the stage of a microscopic projection apparatus, or even on the stage of an ordinary microscope. Electric illuminations must be used for projections The greater the care taken in "indexing" the separate units, the less will be the flicker and the higher the magnification employed. The advantages claimed by this method are: (1) The ease with which a series of sections can be demonstrated to an audience. (2) The unique impression of continuity.

**Horse Sickness in the Transvaal.**—It is stated that the Transvaal Government intends to offer a prize of $125,000 for a method of prevention and cure of horse sickness, a disease which works such frightful havoc among the draught animals in South Africa.

**Sir Henry Acland at Home.**—A life of the late Sir Henry Acland, Regius Professor of Medicine at Oxford from 1858 to 1900, has recently been published. In the chapter on his home life it is narrated that Acland used to address his domestic servants at morning and evening prayers on all kinds of subjects. "Sometimes it would be by showing them his sketches of the Seven Churches, at another it might be a description of General Gordon. These addresses did not always have the desired result. One maid, on being asked if she had understood what he had been telling them, replied, 'I never thought of doing that,' and then she added, 'I look across at the dear master, and I think to myself—You poor, dear, gentleman, how you are enjoying yourself!'"

**Radium Rays.**—E. Rutherford brings some interesting information concerning the three classes of rays obtainable from radium, which element certainly deserves its name. There are the *a*-rays, consisting of heavy, positively charged particles; the *b*-rays, identical with cathode rays and negative electrons, and the *c*-rays which are not deflected by a magnet and can penetrate 8 cm. of aluminium as against the 0.05 cm. of the *b*-rays and 0.0005 cm. of the *a*-rays. The author proves that *a*-rays are also deflected by a magnet of sufficient strength, although the radius of curvature of their path is 39 cm. in a field in which cathode rays would show a radius of curvature of only 0.01 cm. radius. The author proves the magnetic deflection by passing the rays through a number of parallel plates with narrow interspaces, in which the least deflection will lead to absorption. He finds that the velocity of projection of the *a*-rays is about one-tenth of the velocity of light. He supposes that the particles projected are intermediate between atoms and electrons. These *a*-rays are identical with polonium rays, but much faster than canal rays. They are the chief agents in the dissipation of matter and energy from radio-active bodies.—*Scientific American.*

**Famous Singer Studying Medicine.**—Frau Laura Hilgermann, one of the singers at the Imperial Opera in Vienna, is devoting her leisure hours to the study of medicine. She began at the City Hospital, and intends to continue her studies at the university. The long years of suffering of her late husband induced her to take this step, and she intends to utilize her medical skill by treating her colleagues at the opera.—*Evening Post.*

**Bubonic Plague in Sydney.**—The bubonic plague still exists in Sydney. An increase in the number of infected rats and mice is reported and one case has occurred in a human being. This is the first case since June of last year. The source of infection has not been traced so far. The destruction of rats is vigorously prosecuted. No case of plague having occurred in Brisbane for several weeks and no rats having been found infected since June 8, that city has been declared to be free from the disease. All the other Australian States remain free.—*The Lancet.*

**The Life of Mosquitos.**—William Lyman Underwood, writing in the *Popular Science Monthly* with regard to the length of life of the mosquito, says that it is not known just how long mosquitos can live, but their average life is much longer than is ordinarily supposed Thousands of them live through the winter, hibernating in dark places in barns or house cellars. In sparsely settled localities, where they cannot find such places for shelter they live through the winter in hollow trees, in caves and holes under upturned trees. Even though the temperature may fall far below freezing, they are not winter killed, but on the approach of warm weather become active again. Mosquitos are frequently seen flying about in the woods before the snow has wholly left the ground.

**Health Report.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U S. Marine Hospital Service during the week ended September 12, 1903:

### A CASE OF DIFFUSE GONOCOCCUS INFECTION OF THE ENTIRE UPPER EXTREMITY,

WITH NOTES ON THE OCCURRENCE AND COURSE OF GONORRHŒAL SEPTICÆMIA.*

BY CHARLES A. POWERS, M.D.,
DENVER, COLO.

PROFESSOR OF SURGERY IN THE UNIVERSITY OF DENVER; SURGEON TO ST. LUKE'S HOSPITAL.

IN March, 1901, I was asked by the family physician to see L. R., a man of twenty-eight years, whose history was briefly as follows:

On February 21, never having had a previous gonorrhœa, he applied to his physician for the treatment of a specific urethritis which had just made its appearance in the usual way. At this time the physician examined the discharge and found abundant gonococci. The condition was managed in the usual way. There were no bladder or other complications; the man attended to his business as usual, the local condition pursuing an ordinary course. On March 2, nine days after the onset of the urethritis, he complained of a diffuse pain in and about the right elbow. The elbow was found to be moderately swollen, the swelling and pain rapidly increased. On the following day, March 3, he went to bed, the elbow symptoms increasing in severity and extending up and down the limb. His nights were exceedingly bad, they were restless and with frightened dreams. During the nights of March 4 and 5 one-half grain of morphine, together with considerable codeine and trional, failed to give comfort. The temperature was irregular, running from 100° to 102°, the pulse ran from 80 to 90. He felt definitely ill; he was very nervous and apprehensive.

The patient was first seen by me on March 6. At this time the right upper extremity was greatly swollen from the wrist to the shoulder, the swelling being greatest at the elbow, which was two and one half times the circumference of the opposite limb. It was exceedingly tender on pressure all about the elbow, especially tender just above the internal condyle and just in front of and above the external condyle. Movements at the elbow-joint were moderately painful. Fluctuation was not discovered. There was no history of injury and a minute examination of the entire limb failed to reveal evidence of scratch or prick. On the day of this examination the morning temperature was 100½°, the pulse 86 and of fair quality. The patient was very much depressed, exceedingly nervous and apprehensive, irritable, crying, and moaning when the limb was touched.

I readily concurred with the family physician in the diagnosis of a gonococcus infection of the limb. It was impossible at this time to say whether the inflammation had invaded the joint. The limb was confined and wrapped in copious pieces of gauze, which were kept wet with lead and opium wash. Tonics were given.

*Read at the annual meeting of the American Surgical Association, 1903.

On the following day, March 7, the patient felt somewhat better. The temperature and pulse were both a little lower, the general condition of the limb was about the same. A further delay was advised in the thought that the inflammation might tend to subside.

On the next day, March 8, both the local and general conditions were much worse. The patient had had an exceedingly bad night, suffering excruciating pain. The limb was much more swollen, a reddish blush had appeared about the elbow. The tenderness at the points above mentioned became greater. A suggestion of fluctuation appeared. Joint movement at this time gave excruciating pain. The wrist was more swollen and painful, the hand and fingers were puffy. The swelling extended to but not above the shoulder. The urine showed nothing abnormal. The temperature was 103°, the pulse 90 and of fairly good quality. The heart sounds were clear. There was intense frontal headache.

Free incisions were made under ether, the first just above and in front of the internal condyle of the humerus, this being the point of greatest tenderness and the site of semi-fluctuation. The incision was long and was carried to the periosteum of the humerus. It liberated a considerable amount of a thin, clear fluid. From this fluid, as well as from that obtained at other incisions, coverslips and cultures were made by Dr. W. C. Mitchell, Professor of Bacteriology in the University of Denver. Eight or ten more incisions, each two or three inches long and of varying depth, were made about the joint. All of these liberated thin, clear fluid except one incision just below and in front of the external condyle. Here there was a moderate amount of thin pus. Some of the incisions simply went through the deep fascia, others went deeper. The elbow-joint was exposed but not opened, as it did not seem to be definitely distended. All of the wounds were washed out and loosely packed and the limb dressed in the usual way. Dr. Mitchell reported later that the coverslips and cultures (method of Wasserman) showed gonococcus. Those from clear fluid showed a pure culture of gonococcus, the one from the thin pus showed gonococcus and staphylococcus. Dr. Mitchell also examined the urethral secretion, which was at this time rather scanty, and found abundant free gonococci with exceedingly little of the cellular elements. He said that he had rarely seen so little of the latter. I mention this because of the possibility that the almost pure culture of gonococcus in the urethra predisposed to the specific cellulitis of the limb. The family physician, on examining the urethral discharge at its first appearance, had noted the same condition.

On the following day, March 9, the patient felt better, he was almost free from pain. His temperature was normal in the morning and his pulse was very much improved. He was still much depressed and felt definitely ill. The dressings were kept constantly wet with a weak bichloride solution and covered with rubber tissue. The afternoon tempera-

ture was 100°. During the two days following operation the condition remained about the same. The limb tended a little to lessen in size. It remained exceedingly painful on slight pressure everywhere between the wrist and the shoulder. Two days after operation the throat swelled markedly, the whole neck became enlarged and very tender and painful. The pulse went to 100, the heart sounds became very soft and indistinct, and it seemed that a general gonococcus infection had ensued. The next day the left parotid gland was swollen and painful, the right shoulder and pectoral regions were also involved. The condition of the patient seemed precarious. Under simple local and general measures, however, the swelling of the throat, parotid, shoulder, and pectoral region gradually subsided, while the limb proper rather tended to decrease in size. On March 21, thirteen days after operation, the wounds were healing with the exception of the deep one near the internal condyle. This was drained by a small rubber tube. It exuded a large amount of thin, almost clear fluid. The patient's general health was beginning to improve. His nights were better. The limb was still tender and painful. The hand and fingers were pretty well swollen, they were quite tender. The patient was still exceedingly nervous and apprehensive, he was much depressed. At this time the pulse averaged about 80, the temperature was normal in the morning and 99½° to 100½° in the afternoon. The urethra had been treated daily in the usual way. The urethral discharge had nearly disappeared.

As time went by the limb tended still further to decrease in size but the elbow-joint remained tender and painful. Three and one-half weeks after operation all of the incisions were closed except the deepest one. This did not completely close until the end of three months. It was capricious; the discharge would almost cease, then it would suddenly become profuse. And so it was with the swelling of the limb; apparently without cause the elbow and the adjoining forearm and arm would suddenly swell; in a little time the swelling would go down. The wrist and fingers pursued a similar course. At the earliest possible day after the acute symptoms began to subside gentle massage of the wrist, hand and fingers was commenced and the patient was urged to begin motion. But motion was exceedingly painful; the patient was apprehensive, and in spite of best endeavor little progress was made. Six weeks after operation the patient was up and about, a little later he sought suitable baths. Not until the end of three months was the limb in condition to undergo systematic massage. At this time the joints were pretty stiff. For months afterward massage and hot air baths were given; every encouragement was made to increase motion, but in spite of all that could be done the limb remained pretty stiff.

At this time, something over two years having expired, the condition is as follows: The circumference of the limb at the middle of the arm and at the middle of the forearm is considerably less than on the opposite side. The shoulder-joint is free and useful. The elbow-joint is nearly fixed, it is at an angle a little within a right angle. Flexion and extension can be made over an arc of perhaps ten degrees. Pronation and supination of the forearm are nearly complete. There is a pretty good range of motion at the wrist-joint. The index-finger is fairly useful. The other fingers are pretty stiff. Motion in the thumb is good. The thumb can be made to approximate the index-finger very well and the middle finger quite well. The back of the hand is still a little puffy. There has been little or no improvement during the last few months. Th general condition is excellent, the urethra has give no trouble.

At this time we are in possession of sufficient da regarding the secondary manifestations of gonorrh to know that practically all of the tissues of t body may be affected. Most often the proc invades the joints, but the gonococcus has be recovered from the peritoneum, the pleura, t pericardium, myocardium and endocardium, t meninges of the brain and spinal cord, the peri teum, the perichondrium, muscles and tend sheaths, bursæ, fascia, the skin, distant lymph glands, the parotid gland, the kidney, the blo current. It has been customary to group the manifestations under the general term "rheumatism It would seem wise to discard this and substitu septicæmia. It would be quite as rational to spe of a metastatic streptococcus infection of the kn joint as rheumatic as to apply the same term to metastasis due directly to the gonococcus. Wh more absurd than to speak of a gonococcus pleuri or parotitis as rheumatic?

The designation septicæmia covers all. In employment, however, it is necessary to differentia gonorrhœal complication by direct continuity, cystitis, prostatitis, Cowperitis, epididymitis, pe urethral abscess and the like, and reserve the te for true metastatic inflammation. While the on positive cases are those in which the gonococcus c be demonstrated in the tissues at the seat of t metastasis, it is as rational to consider the ordina manifestations consecutive to gonococcus urethrit gonorrhœal as it is to assume a joint affection co plicating a staphylococcus or streptococcus infecti as being due to the same microorganism. The rul which apply to the one govern the other.

Joint affections supposedly due to the gonococcu but not microscopically confirmed have been re ported by numerous observers; with especia emphasis by Claisse,[4] Clarke,[5] Perrin,[8] (diaphragasti pleurisy, femoral phlebitis), Edington,[10] Emery an Glantenay,[11] Halle,[13] Ranzier,[21] Raymond,[22] Thi bierge,[25] Malherbe,[26] Batut.[28] During the past decad an increasing number of observations have bee recorded giving cultural proof that the gonococcus may infect distant tissues in great variety. Thus, Bousquet[8] communicates two cases, the second of which concerned a man twenty-seven years old with gonorrhœa of a month's standing who developed at the level of the internal part of the clavicle a painful swelling which did not extend to the joint. There was no fever, no general reaction, but a week later the joint was seen to be invaded, and on the eighth day fluctuation was discovered. This was incised and about a spoonful of pus evacuated which contained the characteristic microbe of gonorrhœa. Some days later the head of the clavicle was enlarged and there was a partial dislocation above the sternum; spontaneous movements were impossible. Immobilization of the arm brought about a cure; but seven months later there developed a swelling, quite large, of the internal extremity of the clavicle and the corresponding part of the sternum. The subluxation was not reduced, and there was no movement in the sternoclavic joint. The clavicle had a diameter of 3½ cm. and was covered with bony knobs. Houzé[7] states that the nature of so-called gonorrhœal rheumatism has long been discussed; certain authors admit a reflex action, of which the point of departure is the urethra; others think it an accidental complication which they liken to ordinary rheumatism; others that the affection develops from an attack of gonorrhœa but is due to microorganisms other than the gonococcus; others

ely admit the specific character of gonorrhœal umatism. The last theory seems to be the true . Lindemann, Pétrone, Kammerer, and others e found the gonococcus in the exudate of the cted articulations, and Wertheim has observed existence of the microbe of Neisser in the blood illaries of the vesical mucosa; the gonococci were he capillaries and the little pre-capillary veins of the mucous tissue; they were not in the little arteries. is would seem to indicate that the microbe of orrhœa acts as do the ordinary infectious agents.) ley[14] reports an infected elbow-joint in which teriological examination showed abundant gono- i. Moynihan[16] says that of twenty-seven of his s in which a joint effusion was examined, the ococcus was discovered in only eight, the infer- being that the infection is a mixed one. In a of Paldrock's[17] a man of twenty-eight years eloped exudative pleuritis after an attack of orrhœa. Many gonococci were found in the ral exudate. Paulsen[18] reports the case of an nt boy who two days after birth developed ulent ophthalmia. In a few days the left knee affected and two weeks from birth the meta- ophalangeal joint of the right forefinger as as that of the first phalanx was involved. The eral condition was but little disturbed. The ion from the knee showed only gonococci. lsen says that joint metastases in the new-born to gonococci are very rare.

orter[20] states that it is probable that between d 5 per cent. of the cases of gonorrhœa are plicated by arthritis. From the circulating d gonococci have been recovered several times, hat we have absolute proof that this organism cause a general septicæmia or pyæmia and may duce pus wherever localized. The gonorrhœa cause metastases in various distant parts of the y. Such localizations are numerous; in the ts, tendon sheaths and bursæ, pleura, peritoneum, inges, sheaths of nerves, heart wall and valves, en, lungs, kidneys, periosteum, lymphatic glands, cutaneous tissue, skin and parotid gland. A ient of Porter's—coincident with confinement— d acute swelling of the metacarpophalangeal nt, ankle and knee. The gonococcus in pure ture was recovered from the knee-joint contents. another case a man of forty-two years, who had tracted gonorrhœa eight weeks before, developed derate fever, swelling of ankle, shoulder, and ist. In a few days the inflammation subsided in joints except the wrist, which continued swollen. e hand and forearm were much swollen, the ex- ation firm and boggy; there was no redness, tle heat; motion at the wrist, was impossible ithout great pain. In the anatomical snuff-box d over the extensor tendons at the wrist two pparently fluctuating areas existed. On incision e subcutaneous tissue was "porky," the sheaths of e tendons were filled with a gummy, slightly emorrhagic exudate. Communication with the int could be made out. Gonococci were recovered om the pus and granulation tissue in smear and ulture. Recovery followed very slowly, with marked endency to ankylosis. Another case gave the ppearance of an ordinary palmar abscess over the ead of the fifth metacarpal bone, with superficial edness of the skin and great tenderness. At opera- ion no pus was found, but the adjacent joint was filled with a seropurulent material in which were diplococci decolorizing by Gram's stain. No growth on ordinary media. The girl had contracted gonor- hœa four months before and the organisms were still present in the urethra.

Porter says that the gonococcus apparently localizes itself in the subendothelial tissue, there proliferates, and is carried into the joint cavity by the migrating leucocytes or the desquamated epithelium. In the first few days the organisms are infrequent in the joint fluid. At the end of three days the leucocytes and endothelial cells appear in about equal numbers and the gonococci are most abundant. yet are conspicuous for their relative scarcity, occurring in twos and fours within and without the cells. The joint fluid is not a favorable medium for their growth. Young[22] states that all cases of joint effusion in which the gonococcus could be demonstrated at the Johns Hopkins Hospital seemed to demand incision and irrigation.

Considering the early disappearance from the joint cavity the relative scarcity of the organisms, and the well-known difficulties attending their successful cultivation. it is easy to understand why so many aspirations may be sterile. This may show the necessity for early puncture of a joint for diagnostic purposes.

In another article Porter[19] states his belief that the gonococci are capable of living and propagating in the blood. They may be carried by the blood or lymph stream to any of the tissues or organs of the body, and lodging there, produce inflammation, which may be purulent or non-purulent, owing to circumstances which as yet are not understood. True progressive septicæmia is not infrequently due to infection by gonococci.

Senn[23] says that gonorrhœal arthritis occurs in about 2 per cent. of all cases of gonorrhœa. Gonococci may cause general infection and localize in joints without being germinated in a specific urethritis. He believes that the gonococcus does not, as a rule, leave its habitation, the mucous membrane of the urethra or conjunctiva, while it is exerting itself in acute inflammation. It is only when the acute symptoms have subsided that the latent microbe finds its way, through some secondary cause unknown at present, into the general circulation or into the lymphatic system, and subsequently reaches a distant seat.

Ward[24] states that it is obvious that any localized inflammation or sclerosis must be due to toxin locally formed by microbic metastases, while degenerative lesions are due to the general toxæmia, whether absorption takes place from a mucous tract or from such a focus together with secondary metastatic foci. Gonorrhœa is a general toxæmic affection, but the microbes which form the toxin are generally localized on or around a mucous tract. The microbic infection may extend to the organs communicating with the infected tract, or it may penetrate into the tissues, either by direct extension, as in the invasion of the peritoneum through the uterus and Fallopian tubes, or by a process of growth through the mucous membrane affected.

Smith[21] reports the case of a girl nineteen years old in whom a metastatic abscess developed at the middle of the right arm. There were no signs of inflammation save the swelling. Ten days later another abscess appeared beneath and to the inner side of the right scapula. It, also, was unaccompanied by pain, heat, or redness. Gonococci were found in the pus. Hallé[42] reports the case of a woman of thirty years who entered the hospital with generalized gonorrhœal infection with obscure symptoms, going on to hemorrhagic metritis, phlegmonous œdema of the left elbow, endopericarditis and death. The limb early took on the appearance of a phlegmon of rapid course. The skin was tense, red and tender on pressure. There was no sensation of deep fluctuation, but a doughy resistance, especially about the olecranon. A serous fluid was with-

drawn; it was not frankly purulent. The gonococcus was cultivated from this. An incision was made, and serous fluid, turbid and mixed with blood, escaped. The local trouble subsided, but later a hectic fever marked the invasion of the heart and pericardium. Vegetative endocarditis was the lesion predominant at autopsy.

Braquehaye and Servel[44] say that myositis is not so rare a complication of gonorrhœa as has been thought. They have seen two cases in two years. Colombini[45] reports a case of localization of the gonococcus in the right parotid gland; he thinks the gonococci were carried to it by the blood stream. Johnson[48] reports a case (a baby) in which one of the lesions began as a slight inflammation on the right thumb, spreading over the dorsal surface and around to the palm. The left thumb became involved at the metacarpophalangeal joint, the swelling extending to and over the vola. An abscess of the right elbow joint developed. Gonococci were found in the pus. The origin of the infection was possibly a gonorrhœal infection of the umbilicus. The author says that it is generally considered that in order to have a general infection there must be (1) a local infection; (2) a predisposition, as certain patients having a general infection once, have it again with each fresh attack of gonorrhœa.

Prochaska[49] reports the case of a gonorrhœal man of twenty-four who developed a swelling in the region of the left supraclavicular joint. From blood withdrawn from the left vena basilica cultures were made showing gonococci. Thayer and Blumer[84] as well as Wertheim[85] have taught that the gonococci force their way into the epithelium, the connective tissue, and especially into the deeper layer of tissues, where they can cause capillary thrombophlebitis. Perchet and Paolucci believe that they wander by way of the blood and lymph channels. Finger[54] in reporting on 376 cases of joint complication following gonorrhœa speaks of blennorrhagic myositis, periostitis, phlebitis, adenitis, and exanthem. Positive cultural demonstration of gonococci proved a portion of his cases. Finger quotes Ghon and Schlag, who affirm that by migrating into the blood vessels, hidden in the pus corpuscles, the gonococci can cause the various articular, periarticular and perichondritic metastases, and that they can set up suppuration in connective tissue. Drobny, quoted by Ward,[66] states that the gonococci are often extracellular; they are found free as well as in the pus cells. Ward says that in exceptional cases the gonococcus can make its way into the circulation and so reach the cardiac valves and other remote situations. In an individual whose phagocytes are exceptionally susceptible to toxic influences the urethral infection would be imperfectly restrained and thus become very acute. Much toxin would be formed and absorbed. The invasion of the tissues by the microbe would also be very active and the resistance of the guardian wall of inflammatory cells imperfect. The microbes would thus grow into the lymphatics and small veins, and by one route or the other gain the circulation. Here the toxin would have preceded them and already inhibited the leucocytes generally, so the microbes would be enabled to grow in the cardiac valves should they offer a suitable nidus, or might be carried to the peripheral circulation, and there be stranded like sticks and leaves in a back water, in the looped terminal capillaries of the synovial membranes and the slender vessels of the periosteal tissues and tendons. A case of gonorrhœal arthritis of the wrist of an infant (new-born) in which the microbe was found, occurring two weeks after gonorrhœal ophthalmia, gives added evidence of the possibility of a general infection by the gonococcus arising from a local focus other than the urethra. Drobny thinks it possible that the extracellular position of the cocci may be due to paralysis of the leucocytes by toxins, thereby rendering them incapable of surrounding the cocci.

Breton[68] quotes Leloir, who insists on the various infectious forms of gonorrhœa. In a healthy individual the local effects are sometimes the only ones noticed. The general phenomena are unimportant. But if for any reason the vitality of the patient is below par—from hereditary or acquired diathesis, poor hygienic conditions, etc.—the means of resistance are diminished and conditions are favorable for the receptivity, penetration, and multiplication of the organisms. According to the degree of physiological decadence the disorganization of the cells is more or less extensive and the development of the infectious agent more or less rapid. Soon the blood, the organs, the whole economy will be invaded by its toxins, and there will be a general gonorrhœal infection. Breton cites two cases: The first, that of a young man, twenty-one years old, whose gonorrhœa was followed by a generalized infection manifesting itself in ganglionic and splenic adenopathy, endocarditis and infectious periarthrites and a polymorphous erythema (maculo-papulo-vesicular). The attack threatened life, but recovery ensued after two months. The patient suffered from vague pains especially in knees and elbows, swelling and redness at the level of the metacarpophalangeal joint of the right ring (fourth) finger, myosalgia. At the level of the olecranon and over the internal malleoli there were small ulcerating pustules. The gonococcus was demonstrated. The second patient was a man of twenty-five years, whose gonorrhœa was followed by epididymitis, infectious periarthritis and slight general infection. The evolution of these symptoms took three months. There was no fever, but a definite localization in the testicle first, and then in the synovial membranes of the joints. Breton says that organic lesions are the more tenacious the more insidious their appearance, and the duration of the discharge seems directly proportional to the intensity of the general phenomena.

Robinson[71] notes six fatal cases of gonorrhœal origin; four were under his care, while one was communicated to him by De Fleury and one by Hawkins. In five of these endocarditis caused death; meningitis killed the other. The case which Robinson here especially reports is that of a man of thirty-two. The attack at first seemed like the onset of some acute infectious disease. Delirium developed, then coma; death occurred within four days of the time when he was first taken ill. There seemed to be a condition of general hyperæsthesia. The temperature varied from 99° to 105°. On the third day the whole body was dotted with purpuric spots, and it became evident that the patient was suffering from intense blood-poisoning, although no source of infection could be detected. At autopsy gonococci were found in the urethral pus, and the writer is satisfied that the urethra was the original source of the infection. The fluid in the joints was not examined.

I saw a similar case at the County Hospital in Denver some years ago. A woman of thirty-four years was admitted with general arthritic pains and a swollen right knee-joint. There was a gonorrhœal history, gonococci were recovered from the vaginal discharge. On the day after admission she developed symptoms of endocarditis and died within forty-eight hours. An autopsy was not permitted. While the case lacks bacteriological confirmation, I made no doubt at the time that death was due to gonorrhœal

fection. Councilman[52] reported a death from gonorrhœal myocarditis in 1894.

Gershel,[74] in reporting a case of subcutaneous abscesses due to the gonococcus in a child two years of age, looks upon it as one of infection by way of the lymphatics. He found but eleven cases in literature in addition to his, most of them having been collected by Young,[68] who, in a most interesting and valuable article, cites cases of pyonephrosis (single and double), and of diffuse peritonitis culturally confirmed by the presence of the gonococcus.

Kienböck[77] reports on a twenty-six-year-old woman in whom gonorrhœa was followed by paralysis of the right arm, with infiltration of the region of the olecranon, crepitation in the shoulder, changes in the skin and nails. Nobl[78] reports on twenty-three cases of severe gonorrhœal synovial metastases. Of these, eighteen underwent bacteriologic investigation. In thirteen of these the gonococcus was proven, while eleven times a serofibrulent effusion was sterile.

Hunner and Harris[80] report on seven cases of acute gonorrhœal peritonitis, in four of which gonococci were found. All seven cases underwent operation. There were two deaths. Barbiani[81] on polyarthritis with fever, as well as multiple erythema, follow an acute urethritis in a thirty-six-year-old man who was diabetic. Gonococci were recovered from the venous blood.

Seelig[41] believes that muscular atrophy sometimes follows gonorrhœa, and divides the so-called gonorrhœal nerve affections into three groups: (1) neuritis or polyneuritis; (2) Affections of the nerve roots; (3) Meningomyelitis, (*a*) acute, (*b*) chronic.

Balzer[26] refers to the researches of Moltchanon and De Christmas in demonstrating the intensity of the action of gonotoxin on the spinal cord and brain.

Brewer[65] says that gonorrhœal adenitis shows but slight tendency to suppurate, and that when suppuration does occur it is probably due to a mixed infection. The question as to whether the gonococcus alone can produce pus seems to be unsettled. A few cases gathered from literature by Young, together with added instances studied by him in the clinic and laboratory of the Johns Hopkins Hospital, point to the probability that it may. Welch[66] says it is a genuine pus producer.
